To Judy and Carole,

As we worked the long hours on this edition, the two of you gave us encouragement, support, love, and showed exceptional tolerance. We truly appreciate all that you did for us and the time that you allowed us to have in order to make this fourth edition possible. It is with our love and thanks that we dedicate Head and Neck Imaging *to you.*

P.M.S. and H.D.C.

Preface

When we embarked on the fourth edition of *Head and Neck Imaging,* every attempt was made to address the constructive comments we received from readers and reviewers of the third edition. Thus, the organization of this book has been modified and because many readers wanted *Head and Neck Imaging* to serve as a single definitive reference, the fourth edition has been expanded. *Head and Neck Imaging* is now more encyclopedic and detailed, presents more pathology, contains more images, and covers new imaging technologies. Although space limitations and a publishing date never allow a text to be truly all-encompassing, we have attempted to comply as thoroughly as possible with these requests.

The table of contents reflects a re-organization of the book. Compared to the third edition, this edition not only contains several new atlases of normal anatomy, but in many areas there are more detailed discussions of the anatomy. Pertinent physiology is now more thoroughly discussed to allow a better understanding of the function of the specific anatomic units. The pathology sections throughout the book have been enlarged to not only be more inclusive, but also to provide updated and more complete nomenclature and references for each disease. These enlarged sections also discuss pertinent statistics, new genetic concepts relating to a disease, epidemiological data, and contain a more detailed description of the pathology. As pathology is ever more becoming the final arbiter of disease, we believe that *Head and Neck Imaging* should serve, as much as possible, as a resource for this information.

Toward the pursuit of a more complete understanding of the field of head and neck imaging, a chapter discussing the current concepts of the genetics of tumor development and metastasis has been included. This chapter was added because we believe that in the near future, genetic-based imaging, a field now in its infancy, will become a considerably more important technology.

Being an imaging book, many new images have been included and unique older images have been upgraded. In addition, there is now a long overdue new chapter on ultrasound. The inclusion of this chapter fills a deficiency in the prior editions of *Head and Neck Imaging.* There is also a chapter dealing with the use of newer imaging modalities such as PET, MR-spectroscopy, and Thallium-201 imaging. The inclusion of these new sections better rounds out the scope of modalities that are currently being utilized in the field. There are also new chapters on swallowing studies, the trachea, skin and soft tissue lesions, and neural tumor spread. The paranasal sinus plain film section of the third edition was retained, as the growth of emergency room medicine has resulted in a resurgence of the use of these films.

The quality of any book is dependent on the excellence of the contributors' chapters. We were especially fortunate that our contributors submitted thorough, current, and detailed chapters accompanied by high quality images. As editors, it is always a pleasure to work with such wonderful material. In addition to asking some contributors from previous editions to again help us, there are many new contributors to the fourth edition. We are especially pleased with the enthusiastic contributions made by these new contributors, as these radiologists represent the future of the field.

Last, but far from least, the editors want to thank all of the editorial people at Saunders/Mosby, without whose guidance, patience, and knowledgeable advice this edition could not have been made. It was through their efforts that a new fresh format for the book was created. This includes more reference charts and tables, and a ''new look'' that we believe will make the fourth edition more accessible to our readers.

It is our hope that our readers will utilize the fourth edition of *Head and Neck Imaging* to not only help them in the diagnosis of head and neck imaging cases, but as a resource for the knowledge that is necessary to attain a well informed understanding of this fascinating and rewarding field.

Sincerely,

P.M.S.
H.D.C.

CONCLUSION

INTRODUCTION

Traditionally, congenital malformations have been defined by their effect on gross anatomy and classified by phenotypic similarities.[1] Clinically valid constellations of pathology have been called syndromes and named for the authors who reported them. Recent work has begun to elucidate the molecular bases for the phenotypes observed to provide an improved method for defining disease entities.[2–25] This chapter reviews selected congenital malformations of the midface, both classically and as examples of the evolving classification by molecular genetics. Limitations in the information available make this approach uneven, but still useful.

Craniofacial malformations result from misregulation of normal tissue patterning.[2] In utero, signal transduction pathways normally relay information from outside the cell, through the plasma membrane and cytoplasm, into the nucleus in order to regulate and coordinate the expression of target genes (Fig. 1-1). From the nucleus, related information then passes outward to alter cytoplasmic structures, to modulate the cell response to incoming signals, and to coordinate activities of other cells, nearby or distant.[2] The signals employed often take the form of *ligands*, which may be diffusable (e.g., growth factors) or stationary (e.g., extracellular matrix–associated proteins). The ligands bind to molecules designated transmembrane receptors.[2] These transmembrane receptors present an extracellular domain, which can interact with external signals; a transmembrane domain, which spans the cell membrane; and an intracellular domain, which effects changes within the cell.[2] Binding of the ligand to the extracellular domain of the receptor alters receptor conformation and initiates changes that propagate along the molecule to alter enzymatic activity or regulatory properties within the intracellular domain. Receptors such as fibroblast growth factor receptors (FGFRs) and bone mophogenic protein (BMP) receptor are often kinases that catalyze the transfer of a phosphate group from adenosine triphosphate (ATP) to the side chains of amino acids within other proteins (the substrates).[2] The substrates may themselves be kinases. Therefore, binding of ligand to the extracellular domain of the receptor may cause phosphorylation of the intracellular domain of the receptor, leading to phosphorylation of intracellular substrates and altered

FIGURE 1-1 Cell signaling and signal transduction. Diagramatic representation. The outer square represents the cell surface. Ligand binding to the extracellular domain of the transmembrane receptor conveys information to the nucleus, where it affects gene regulation and transcription, alterations in cell shape, proliferation, migration, differentiation, apoptosis, and coordination of cell populations for further embryogenesis. (From Nuckolls GH, Shum L, Slavkin HC. Progress toward understanding craniofacial malformations. Cleft Palate-Craniofac J 1999;36:12– 26.)

activity of other intracellular proteins. In like fashion, interactions among proteins to form a complex can alter their conformation and activity, either subtly or substantially.[2] Complexes of proteins designated transcription factors associate with DNA to increase or decrease transcription of specific genes and to modify protein synthesis qualitatively and/ or quantitatively. Through these changes in protein activity, signals are propagated and integrated into circuits or networks that regulate gene expression and control cell proliferation, migration, differentiation, bilateral symmetry, and even death (apoptosis).[2] The coordinated control of cell populations is fundamental to the formation of complex structures such as the human face during embryonic development.[1–25] Derangements in this coordinated signaling lead to the malformations observed. Figures 1-2 and 1-3 depict the developing forebrain and its relationships to the developing face.[5–7]

EMBRYOLOGY OF THE FACE AND SKULL

Development of the Face and Jaws

The tissue that gives rise to the face and jaws derives from three major sources (Figs. 1-2 and 1-3):

1. The *ectoderm* provides the surface cover, and by ectodermal–mesenchymal interactions helps to pattern the developing structures.[3, 4, 20, 21]
2. *Neural crest cells* provide most of the facial mesenchyme.[3, 4, 7, 17, 23]
3. The *paraxial and prechordal mesoderm* contribute tissue that evolves into the myoblasts of the voluntary craniofacial muscles.[4]

The first sign of the future face is a surface depression, the stomodeum, situated just below the developing brain (Fig. 1-4). The ectoderm that overlies the early forebrain extends into the stomodeum, where it lies adjacent to the developing foregut. The junction between the surface ectoderm and the subjacent endoderm is called the oropharyngeal membrane. The line of attachment of the oropharyngeal membrane corresponds to Waldeyer's ring. Dissolution of the oropharyngeal membrane by the end of

FIGURE 1-3 **A**, Schematic representation of the longitudinal organization of the forebrain. The optic stalk appears as a black oval. Black lines indicate the boundary of the telencephalic vesicle and the contours of the medial and lateral ganglionic eminences within it. Note the relationships among the alar-basal junction, the optic stalk, the chiasmatic plate anlage (*ch*), and the retrochiasmatic (rch) (anterobasal region) of the basal plate, and the relationships among the notochord, floor plate, prechordal floor, and infundibulum. **B**, Molecular designation of topography. Compare the topographc distribution of Sonic Hedgehog (*Shh*), *Nkx-2.2*, *BF-1*, and *noggin* with the anatomic locations shown in **A**. *Shh* is a gene that encodes a diffusable protein implicated in specifying the notochord and floor plate of the neural tube. It helps to regulate *Nkx-2.2*. *Nkx-2.2* is a homeobox gene first detectable at the 1-somite stage in a median rostral region of the neural plate just anterior to the rostral tip of the notochoral plate. *Shh* and *Nkx-2.2* define adjacent and nonoverlapping longitudinal neuroepithelial zones that extend along the entire central nervous system (CNS) and end anteriorly, where they cross the midline in the optochiasmatic region. Brain factor 1 (BF-1) may be regarded as an alar plate marker of the prosencephalon. It is expressed in most of the telencephalon, the preoptic region, the adjoining one half of the optic stalk, and one half of the optic cup. It is reciprocal to the expression of BF-2 in the other halves of the optic stalk and cup. *noggin* is a gene that encodes a secreted polypeptide with neural-inducing properties. It is expresssed in the roof plate along the entire neural axis. Its anterior end approximates the anterior extent of the prosencephalic vesicle and does not enter the lamina terminalis. *Rh*, rhombencephalon; *me*, mesencephalon; *cx*, embryonic cerebral cortex; *lge*, lateral ganglionic eminence; *mge*, medial ganglionic eminence. The anterior-medial alar region of the neural plate maps to the lamina terminalis of the brain (square with asterisk). *Shh* present in the mge is not shown for simplicity. **C**, Neural crest migration. Chick embryo model. The facial mesenchyme derives from cohorts of neural crest cells that migrate to specified regions within the developing face and branchial arches from defined segments of the forebrain, midbrain, and hindbrain rhombomeres r1 to r7. Note the relationships of the pathways of migration to the optic vesicle, the otic placode, and the developing cranial nerves 5, 7/8, and 9/10. Clonal variations and mutations in specific cohorts of neural crest cells can lead to malformations restricted to subsets of cells in specific topographies. In mammals, r2, r4, and r6 send streams of neural crest cells into branchial arches 1, 2, and 3, respectively. The streams of neural crest cells that arise in r3 and r5 turn sharply to join the streams from adjacent rhombomeres. (**A** and **B** from Shimamura K et al. Longitudinal organization of the anterior neural plate and neural tube. Development 1995;121:3923–3933. **C** from Köntges G, Lumsden A. Rhombencephalic neural crest segmentation is preserved throughout craniofacial ontogeny. Development 1996;122:3229–3242.)

FIGURE 1-4 Embryogenesis of the face from 4 to 10 wg. See text. (Modified from Carlson BM. Human Embryology and Developmental Biology, 2nd ed. St. Louis: CV Mosby, 1999.)

the fourth week of gestation (wg) permits communication between the mouth and the foregut.[3] Waldeyer's ring connects the nasopharyngeal adenoids, the palatine tonsils, and the lingual tonsils.[14] The depth of Waldeyer's ring within the mouth of the newborn indicates the extent to which facial development results from thickening of the surface tissue external to the original ectodermal level.[14]

During the fourth week of gestation (wg), neural crest cells migrate to the developing face from the lower forebrain, the midbrain, and rhombomeres 1 and 2 of the upper hindbrain (Fig. 1-3C). Neural crest cells also migrate to other pharyngeal arches from the lower rhombomeres.[3, 6, 7] These migratory neural crest cells are the predominant source of facial connective tissue, including cartilage, bone, and ligaments. Since the neural crest cells migrate to the face as cohorts of cells from different portions of the brain, they carry with them different developmental programs. Mutations arising in the premigratory or early migratory neural crest cells may affect one specific clone of cells, which then carries that mutation to a predestined site in the face.

At 4 wg, five identifiable primordia surround the stomodeum (Fig. 1-4). The single, unpaired frontonasal prominence lies in the midline just superior to the

Copyright © 2003, Mosby, Inc. All rights reserved.

stomodeum. Embryologically, this prominence is related to the forebrain. Paired maxillary prominences lie on each side of the stomodeum superiorly, and paired mandibular prominences lie on each side of the stomodeum inferiorly. These processes originate from the first branchial (pharyngeal) arch.[3, 11] During the fourth to eighth wg, the frontonasal prominence gives rise to the median facial structures, and the paired maxillary and mandibular prominences give rise to the lateral facial structures.[3] Since the medial and lateral structures derive from different tissues, malformations of the face tend to affect either the median or the lateral structures separately, or their lines of junction.

By the end of the fourth wg, even before the neural folds close, paired thickenings of ectoderm appear on the surface of the frontonasal prominence just superolateral to the stomodeum.[3] These oval nasal placodes, located at 1 and 11 o'clock, give rise to the future nose and nasal cavities. Development of the nasal placodes (and the lens placodes) requires the paired box gene *Pax 6*.[3] In the absence of *Pax 6*, neither the nasal nor the lens placode develops.[3] During the fifth wg, mesenchyme in the margins of the nasal placodes proliferates to form horseshoe-shaped elevations (Fig. 1-4). The medial limbs of the horseshoes are designated the nasomedial processes. The lateral limbs of the horseshoes are designated the nasolateral processes. The nasomedial processes are longer than the nasolateral processes.[4] The tissue surrounding the placodes thickens and elevates, so the nasal placodes appear to become recessed within depressions in the surrounding tissue. The depressions are then designated nasal pits. The nasal pits are the primordia of the anterior nares (the future nostrils) and the nasal cavities.[4]

From 4 to 5 wg, the mandibular processes enlarge on both sides. From 5½ to 8 wg, their medial components merge in the midline, forming the point of the lower jaw (mentum) (Fig. 1-4).[3] Incomplete fusion at the mentum leaves the common midline chin dimple.[4] From 4 to 6 wg, the paired maxillary processes grow toward each other and toward the paired nasomedial processes.[3] The maxillary processes will ultimately give rise to the lateral two thirds of the upper jaw, the upper teeth (except for the incisors), and the palatal shelves that contribute to the hard palate. By the end of the sixth wg, the nasolateral processes begin to merge with the maxillary processes to form the ala nasi and the lateral border of the nostril on both sides (Fig. 1-4).[3] Along the junctions between the maxillary and nasolateral processes on both sides, nasolacrimal grooves still extend between the developing nose and eyes. The ectoderm along the floor of these grooves thickens to form solid epithelial cords, which detach from the grooves and then canalize to form the nasolacrimal ducts and lacrimal sacs. By the late fetal period, the nasolacrimal ducts extend from the medial corners of the eyes to the inferior meatuses in the lateral walls of the nasal cavity.[4] These ducts usually become completely patent only after birth. The nasomedial processes on both sides remain unfused.

From the sixth to the eighth wg, the cheeks and the corners of the mouth form by the merging of the maxillary and mandibular processes. The upper lip is completed during the seventh and eighth wg (Fig. 1-4).[3] The expanding nasomedial processes merge with the superficial regions of the maxillary processes on both sides along epithelial seams (fusion lines) designated nasal fins.[3] Mesenchyme penetrates the nasal fins, forms a continuous union between the nasomedial and the maxillary processes, and completes much of the upper lip and upper jaw on both sides. The two nasomedial processes then merge with each other across the midline to form the intermaxillary segment. The fusion of the two nasomedial processes displaces the frontonasal prominence posteriorly. Therefore, the frontonasal prominence does not contribute significantly to the definitive upper lip, jaw, or nasal tip, even though it formed a prominent portion of the stomodeal border at 4 to 5 wg.[3] The intermaxillary segment formed by the nasomedial processes is the precursor for the medial portion of the upper lip (the prolabium), the premaxillary component of the upper jaw containing the four upper incisors (the gnathogingival segment), and a triangular midline anterior wedge of palate (the primary palate) (Fig. 1-5).[3] The primary palate will later become continuous with the most rostral portion of the nasal septum. Fusion of the paired nasomedial processes also forms the tip and the crest of the nose and a portion of the nasal septum.[3]

From the sixth wg, the primordia of the auricles of the external ear begin to develop (Fig. 1-4). By the seventh wg, six mesenchymal swellings designated auricular hillocks form around the first pharyngeal groove on each side: three from the first branchial arch and three from the second branchial arch[3] (see the section on Hemifacial Microsomia). The auricular hillocks will merge with each other to form the

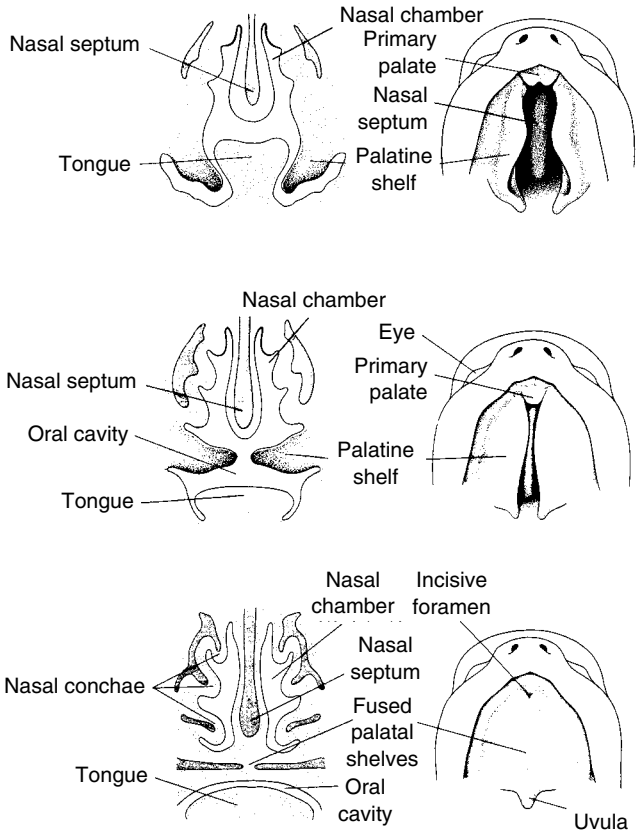

FIGURE 1-5 Embryogenesis of the palate from 6½ to 10 wg. (From Langman J. Medical Embryology: Human Development, Normal and Abnormal, 2nd ed. Baltimore: Williams & Wilkins, 1969.)

auricle. The groove between them will form the external auditory meatus.[3] Initially, the external ears are located inferomedially in the neck. As the mandible develops, the ears ascend laterally to the sides of the head at the level of the eyes.[4] During this time, descent of the nose and medial migration of the orbits above the nose are also observed.

Until the end of the sixth wg, the primitive jaws are composed of masses of mesenchyme.[4] A linear thickening of ectoderm, designated the labiogingival lamina, then begins to grow into the underlying mesenchyme. This lamina ''carves out'' a labiogingival groove, creating the separate lips and gingiva. It then degenerates, except in the midline, leaving the labiogingival groove between the lips and the gingivae, and a midline frenulum for the upper lip.[3, 4] Separation of the lips from the gingivae occurs only after the mesenchyme within the individual facial processes merge to form the upper lip, and is not found in regions where the facial processes fail to merge successfully (e.g., such a sulcus is deficient in patients with complete cleft lips).

Once the basic facial structures take shape, they are invaded by mesodermal cells associated with the first and second pharyngeal arches. These cells form (1) the muscles of mastication (first arch derivatives innervated by cranial nerve 5) and (2) the muscles of facial expression (second arch derivatives innervated by cranial nerve 7).[3] The relative proportions of the facial structures change during life. The midface remains underdeveloped during embryogenesis and early postnatal life and grows to full size later.[3] The mandible is initially small and shows later ''catch-up'' growth.

Molecular Signaling and Tissue Patterning in the Face

The facial primordia are analogous to limb buds and depend on highly similar molecular signaling for patterning and elongation. In both the face and limbs, for example, (1) mesenchymal–ectodermal interactions pattern the tissue, (2) sonic hedgehog, fibroblast growth factor (FGF), and retinoic acid signaling are critical for growth, (3) aristaless-like homeobox genes (*Prx1, Prx2, Alx3, Alx4*) serve as upstream regulators of sonic hedgehog, and (4) the homeobox gene *Msx1* is expressed in the rapidly proliferating mesenchyme near to the leading edge of the process.[3, 5, 11, 12] In the face, sonic hedgehog may be the morphogenic organizer, while fibroblast growth factors may serve as the stimuli for mesenchymal outgrowth.[3]

Facial and limb malformations are known to result from deficiency or excess of molecular signaling. Similar phenotypes, such as clefting, may result from either deficiency of the appropriate midline tissue or such excess of other midline tissue that the appropriate processes cannot meet to fuse in the midline. In experimental animals, *reduced* retinoic acid signaling diminishes expression of sonic hedgehog and fibroblast growth factor 8 (FGF8) in the mesenchyme, increases apoptosis (programmed cell death) locally, and decreases proliferation of tissue in the forebrain and frontonasal processes. These animals show holoprosencephalic phenotypes with hypoplastic forebrain, fused eyes, and absence of structures derived from the frontonasal process. Timely replacement of retinoic acid prevents this malformation.[5] Conversely, excess sonic hedgehog stimulates frontonasal growth and widens the frontonasal process (an average of 48%), so that (1) the developing palatal shelves fail to abut, leaving a cleft palate, and (2) more severe phenotypes show ectopic midfacial structures with duplication of the nasal bone.[12, 15]

Development of the Palate

The palate is formed from the seventh to the tenth wg from three primordia: an unpaired median palatine process and paired lateral palatine processes (Fig. 1-5).[6, 8, 9] The newly merged nasomedial processes form the median palatine process. This grows posteriorly to form a triangular bony structure designated the primary palate. In adult life, this portion is called the premaxillary component of the maxilla and gives origin to the four upper incisors.[3] The incisive foramen marks the posterior midline extent of the premaxilla. The lateral palatine processes first appear during the sixth wg and grow vertically downward on both sides of the tongue.[3] The growth of the palatal shelves also resembles the growth of the limb bud. It involves both ectodermal–mesenchymal interaction and growth factors like epidermal growth factor (EGF) and transforming growth factor alpha (TGF-alpha). The growing palatal processes may even display an apical ectodermal thickening similar to the apical ectodermal ridge of the limb bud.[3] During the seventh wg, hydration of hyaluronic acid within the palatal processes generates an intrinsic shelf-elevating force that elevates the palatal shelves from their early vertical position alongside the tongue into a definitive horizontal position above the dorsum of the tongue.[11] The epithelial cells along the medial edge of each palatal shelf contact each other and fuse together along an epithelial seam.[11] The two palatal shelves also fuse with the triangular primary palate anteromedially to form the Y-shaped fusion line (Fig 1-5). The success or failure of palatal fusion is strongly influenced by genetics and by physical constraints of the space available within the dividing nasooral cavity.

Following fusion of the palatal shelves, the seam cells migrate, orally and nasally, into epithelial triangles and subsequently into the oral and nasal epithelia.[23] Developmental programs for epithelial–mesenchymal interactions promote regionally specific palatal epithelial differentiation into nasal pseudostratified ciliated columnar cells and oral stratified squamous cells.[11] Growth factors localized within the developing palate appear to underlie the epithelial–mesenchymal interactions. Fibroblast growth factor 7 (FGF7), for example, is synthesized by the mesenchymal cells, while its receptor is synthesized in the overlying epithelia, establishing an integrated signaling system.[2]

Development of the Nasal Cavities and Septum

From 5 wg, the nasal pits deepen toward the oral cavity, forming substantial depressions. By 6½ wg, only a thin oronasal membrane separates the oral cavity from the nasal

Copyright © 2003, Mosby, Inc. All rights reserved.

cavities.[3] This oronasal membrane then breaks down, so that the oral cavity can communicate with the nasal cavities through openings posterior to the primary palate.[3] These openings are designated the nasal choanae. Fusion of the two palatal shelves then lengthens the nasal cavity and carries the communication posteriorly to the upper pharynx.[3] The nasal septum grows down from the frontonasal prominence to reach the level of the palatal shelves when the shelves fuse to form the definitive secondary palate. Anteriorly, the septum is continuous with the primary palate.[11] The actual fusion of the palate begins posterior to (not at) the incisive foramen and extends from there, both anteriorly and posteriorly, to complete the formation of the palate. The point of fusion of the secondary palatal shelves with the primary palate is marked by the incisive foramen.[11]

The Facial Skeleton

The cartilage of the nasal capsule is the foundation of the upper part of the face (Figs. 1-6 and 1-7).[24] The bony elements of the facial skeleton appear around it and replace it in part. The lateral masses of the ethmoid form by enchondral ossification of the nasal capsule. The frontal processes of the maxillary bones, the premaxillary bone, the nasal bones, the lacrimal bones, and the palatine bones all form in membrane in close relationship with the roof and lateral walls of the cartilaginous nasal capsule.[24] The vomer develops in membrane in relation to the perichondrium of the septal process.[24] Eventually, nearly all of the nasal capsule becomes ossified or atrophied. All that remains of the cartilage of the nasal capsule in adults is the anterior part of the nasal septum and the alar cartilages that surround the nostrils.

Specifically, the midline septal cartilage is directly continuous with the cartilaginous skull base. At birth, the skull base has three major ossification centers: the *basiocipital* center, the *basisphenoidal* center, and the *presphenoidal* center. The septal cartilage has not yet ossified. The lateral masses of the ethmoid have ossified, forming paired paramedian bones, but the cribriform plate is still cartilaginous or fibrous.[24] At birth, therefore, the entire midline of the face may be a lucent strip of cartilage situated between the paired ossifications in the lateral masses of the ethmoids. This lucent midline can simulate a midline cleft on imaging studies. The septal cartilage extends along the midline from the nares to the presphenoid bone.[24] Anteriorly and inferiorly, the septal cartilage attaches to the premaxillary bone by fibrous tissue.[24] Posteriorly, the septal cartilage is continuous with the cartilage of the cranial base. Inferiorly, the lower edge of the septal cartilage is slotted into a U- or V-shaped groove that runs along the entire upper edge of the vomer (Figs. 1-7 to 1-9).[24] This groove is designated the vomerine groove. It should not be mistaken for a midline cleft in the septum.

At about the time of birth or during the first year of life, a fourth center, the *mesethmoidal* center, appears in the septal cartilage anterior to the cranial base. This center will form the perpendicular plate of the ethmoid.[24] The residual portion of still unossified septal cartilage that extends posterosuperiorly toward the cranial base between the perpendicular plate of the ethmoid and the vomer is designated the sphenoidal tail of the septal cartilage.[24] Initially, the ossifying perpendicular plate is separated from the rest of the facial skeleton by (1) the unossified cartilage or fibrous tissue of the cribriform plates and (2) the sphenoidal tail (Figs. 1-7 to 1-9). At about the third to sixth year, the lateral masses of the ethmoid and the perpendicular plate of the ethmoid become united across the roof of the nasal cavity by ossification of the cribriform plate.[24, 25]

Somewhat later, the perpendicular plate unites with the vomer below.[24] As the two bones approach, the vomerine

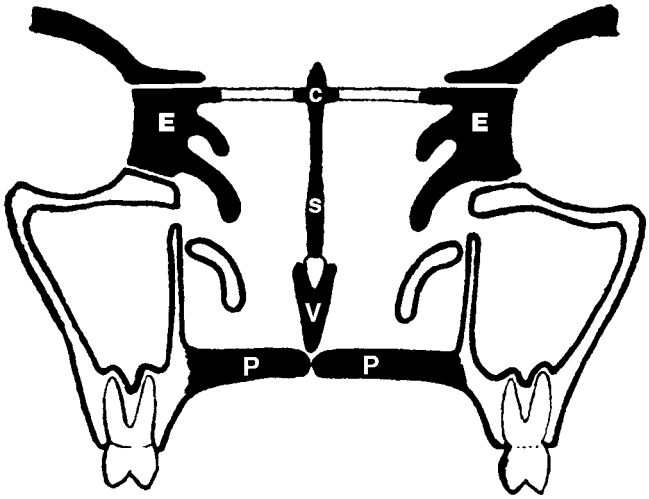

FIGURE 1-7 Diagram of the pattern of ossification around the nasal cavity. The ossified crista (*C*) and septal cartilage (*S*) form a ''cristal'' cross that is isolated from the lateral ethmoid centers (*E*) by the unossified cribriform plates and from the vomer (*V*) by the sphenoidal tail. Although the maxillae are ossified, only the palatal shelves (*P*) have been inked in to emphasize their relationships to the vomer. (Modified from Scott JH. The cartilage of the nasal septum (a contribution to the study of facial growth). Br Dent J 1953;95:37.)

FIGURE 1-8 Normal patterns of ossification of the nasal capsule, as shown by direct coronal CT in progressively older patients**. A** and **B**, Four-month-old girl. The lateral ethmoid centers and a small segment of vomer are ossified. The midline septal cartilage is entirely unossified. **C** and **D**, Five-month-old boy. The lateral ethmoid centers, the palatal shelves, the vomer, and the tip (*white arrow)* of the crista galli are ossified. The widened midportion of the septum (*white arrowhead* in **C**) is designated the septal diamond. The two sides of the vomerine groove give the posterior septum a bilaminar appearance (*white arrowhead* in **D**).

Illustration continued on following page

groove may become converted into a vomerine tunnel. This should not be mistaken for a bony canal around a dermal sinus or cephalocele. Growth of the septal cartilage continues for a short period after craniofacial union is complete. This may explain the common deflection of the nasal septum away from the midline.[24]

Because the appearance of the nasal septum varies with the patient's age, one must interpret imaging ''evidence'' of midline defects and sinus tracts carefully. Review of the CT appearance of the midline anterior fossa and nasal septum in 100 children aged 2 days to 18 years revealed the following normal patterns (Figs. 1-7 to 1-9):[1, 26]

1. The lateral ethmoid centers are ossified in all patients.
2. No *midline* ossifications of the anterior fossa or septum are present in 14% of patients less than 1 year of age.
3. The cribriform plate is not ossified in patients less than 2 months of age. It can be ossified from 2 to 8 months of age. It is fused across the midline from 8 months on.
4. The tip of the crista can be ossified from 2 days on. It is invariably ossified from 2½ years on.
5. The crista plus the cribriform plate forms a _/_ os-

VIEW IMAGE

FIGURE 1-9 Normal pattern of ossification as shown on axial noncontrast CT. In the 11-month-old girl shown in **A** to **C**, serial axial images display the following: (**A**) The normal, thin nasal septum with faint parallel ossifications representing the vomer, (**B**) the normal midline defect (*black arrowhead*) anterior to the normal parallel ossification within the closing cribriform plates and crista, and (**C**) the upper portion of the crista (*arrowhead*) with a small fossa anterior to it. Comparing these images with the coronal sections in Figures 1-6 through 1-8 aids understanding of how the parallel ossifications arise. **D**, Twelve-year-old boy. The foramen cecum (*black arrowhead*) is a well-defined ostium situated just anterior to the diamond shaped ossified crista galli.

sification, with *no* ossification of the perpendicular plate, in patients 2 months to 5 months of age.

6. The ossified crista, cribriform plate, and perpendicular plate can form a bony ''cristal cross'' from 4 months on. These ossifications invariably form a cross from 11 months on.
7. A zone of *un*ossified tissue is seen within the crista in 60% of patients with a cristal cross. Such ostia can be present at any age from 4 months on.
8. The perpendicular plate of the ethmoid can be ossified as a single plate in patients aged 11 months to 18 years. It is ossified in the vast majority of patients older than 2 years.
9. The perpendicular plate is ossified as two parallel laminae in 15% of patients.
10. The nasal septum is widest at the midpoint of its vertical height in nearly all patients of all ages. This widening is designated the septal diamond.
11. The perpendicular plate widens inferiorly or splits to form an inverted Y at the septal diamond in 30% of patients, all older than 6 years of age.
12. The perpendicular plate reaches as far inferiorly as the septal diamond in 32% of all patients, 92% after age 6 years and 100% after age 13 years.

The ossified vomer exhibits a V- or Y-shaped superior border in 80% of patients at any age. The vomerine ossification appears as a single point anteriorly and as a V or Y posteriorly in 21% of patients. In 8% it is seen only as a single point.

In the *normal* patient then, one may expect to see no ossification in the midline of children under 1 year of age, an unossified zone within 60% of the cristal crosses, a ''bilaminar'' perpendicular plate of ethmoid in 15%, and a V- or Y-shaped upper surface of the vomer in at least 80% of patients (Figs. 1-6 and 1-7). These should not be overinterpreted as pathology.

The development of the ethmoid labyrinth is often asymmetric in contour and position.[27] As a consequence, 48% of normal patients show contour asymmetry of the fovea ethmoidalis with flattening of the ethmoid roof on one side, and 9.5% show an asymmetric position of the fovea ethmoidalis.[27] Of those with positional asymmetry, the

Copyright © 2003, Mosby, Inc. All rights reserved.

fovea is lower on the right in 63% and lower on the left in 37%.[27] This normal variation must not be misinterpreted as pathology.

TORI PALATINUS, MAXILLARIS, AND MANDIBULARIS

Torus palatinus is a benign thickening of normal cortical and medullary bone on the oral surface of the hard palate (Fig. 1-10).[28–35] It is covered by a thin, pale mucosa. The torus typically aligns along the median intermaxillary-interpalatine suture, protrudes downward from the apex of the palatal arch, and extends to both sides, approximately symmetrically. The regions of the palatal rugae and the greater palatine foramina are usually spared, so the tori have a ''faceted,'' triangular/diamond configuration.[32] The nasal aspect of the hard palate is never affected by simple torus palatinus.[31] *Torus maxillaris* signifies one or multiple unilateral or bilateral hyperostoses arising from the alveolar portion of the maxilla, usually in the molar region. Torus maxillaris internus arises along the lingual surface of the dental arch opposite the roots of the molars and may coalesce into lobular or irregular masses. Torus maxillaris externus appears as broader, sausage-shaped, or alate expansion(s) of the buccal aspect of the superior alveolar ridge.[28–32] *Torus mandibularis* signifies unilateral or bilateral hyperostoses arising along the lingual surface of the mandible between the alveolar border and the mylohyoid line (Fig. 1-11). They usually are found in relation to the apex of the second premolar[33] opposite the mental foramen.[29–32] *Multiple tori* may occur together. Tori maxillaris and mandibularis are found more commonly in skulls with torus palatinus (Figs. 1-10 and 1-11). Buccal hyperostoses of the maxilla and mandible commonly occur together in both sexes.[22] Torus palatinus and torus mandibularis may both be associated with a thick posterior wall of the glenoid fossa (tympanic plate).[37]

Torus palatinus is found in 19% to 60% of diverse ethnic

VIEW IMAGE

populations and in 20.9% of 2478 dental subjects of mixed heritage in the United States.[35, 37, 38] Tori have a distinct tendency toward heritability, with Oriental and Amerindian populations showing a particularly high incidence (44% to 60%).[30] In one study of approximately 150 Japanese families, Suzuki and Sakai showed that the incidence of torus palatinus in parents of Japanese children was 87.7% if the child had a torus but only 23.8% if the child had no torus.[33] Further, the larger the torus in the parent, the greater the incidence of tori in the children, the earlier their appearance, and the larger their size in the offspring.[19]

Tori are found in approximately 2% of newborns and increase in incidence with age.[34, 39, 40] After the newborn period, torus palatinus is approximately twice as common in females as in males.[35, 38–42] Tori grow as the patients grow, until maturity at 20 to 30 years of age, and then stabilize.[30, 33, 42] Unusual tori continue to increase in size in later decades of life.[30] Woo found no sex difference in the size or shape of the tori palatini in 2348 skulls.[30]

Torus palatinus is classified by shape into four major categories[34, 35]:

1. *Flat torus* is a smooth, bilaterally symmetric, broad-based exostosis that is mildly elevated, slightly convex, and oriented along the midline intermaxillary-interpalatine suture of the palate.
2. *Spindle torus* is a midline palatine ridge (the cresta palatina), which may contain a prominent median groove, signifying bilateral origin.
3. *Nodular torus* is a more bulbous hyperostosis formed from close juxtaposition of paired bilateral hemitori or from multiple smooth, discrete, bony protuberances.
4. *Lobular torus* is a large, pedunculated, mushroom-like mass that typically arises from a single base to form multiple secondary lobules separated by variably deep grooves.

Overall, flat and spindle-shaped tori palatini are the most common (86% combined). The larger nodular and lobular forms are seen in only 6% to 8% of patients.[21]

Most tori palatini are small, clinically insignificant, incidental findings on imaging studies. Only 22% are more than 2 cm in length.[42] Very rarely, large tori may restrict motion of the tongue, distort the oral air cavity, and cause speech disturbance. Substantial tori may have to be resected before a patient can be fitted with dental prostheses.

FACIAL CLEFTS

Deranged development of the frontonasal process and/or failure of adjacent processes to merge successfully results in

FIGURE 1-12 Facial clefting. **A**, Absence of the intermaxillary segment with *hypo*telorism. The maxillary processes form the normal lateral thirds of the upper lips. The midline rectangular defect indicates the site of the deficient intermaxillary segment with absent prolabium, incisors, and primary palate. There was consequent clefting of the secondary palate. Absent intermaxillary segment with hypotelorism signifies a high likelihood of holoprosencephaly. **B**, True midline cleft of the upper lip and philtrum with *hyper*telorism. The nose is normal. A 7-month-old girl with transethmoidal cephalocele and left optic nerve dysplasia (morning glory syndrome). True midline cleft lip signifies the high likelikhood of midline craniofaciocerebral and optic dysraphysm. **C** and **D**, Midline cleft lip is also found in association with Mohr syndrome (orofacial digital syndrome II [OFD II]). The presence of reduplicated great toes bilaterally helps to identify OFD II and to distinguish it from OFD I.

a coherent series of malformations. Insufficiency of the frontonasal and nasomedial processes may result in hypoplasia or absence of the nose and intermaxillary segment, with a roughly rectangular defect in the middle one third of the upper lip, absence of the incisors, absence of the primary palate with a cleft in the secondary palate, and *hypo*telorism. This is one common manifestation of holoprosencephaly[1, 6, 43, 44] (Fig. 1-12A). Failure of the two nasomedial processes to merge in the midline produces the rarer, true midline cleft lip and palate with *hyper*telorism. This is typically associated with cleft primary palate, diastasis of the medial incisors, double frenulum of the upper lip, dehiscence of the skull base, and basal encephaloceles (Fig. 1-12B). True midline cleft is also a feature of Mohr syndrome (Fig. 1-12D). Failure of the nasomedial processes to merge with the maxillary processes on one or both sides produces the typical unilateral or bilateral common cleft lip and/or cleft palate (Fig. 1-13). Discordant growth of the two divided processes may then result in offset of the premaxillary segment from the maxillary segment, a

widened nostril, a depressed ala nasi, and an anomalous nasal septum.[4] Failure to merge the nasolateral process with the maxillary process results in an oblique facial cleft extending from the inner canthus of the eye into the nose (Fig. 1-14). This cleft may occur in association with bilateral common cleft lip and/or palate. Failure to merge the maxillary with the mandibular process, unilaterally or bilaterally, results in a transverse facial cleft, also designated ''wolf mouth'' or macrostomia[45] (Fig. 1-15). The transverse cleft may occur in isolation or as part of syndromes such as hemifacial microsomia (see the section on Hemifacial Microsomia). Clefts that do not align along known lines of embryonic fusion likely represent the syndrome of amniotic bands (see the section on Syndrome of Amniotic Bands) (Fig. 1-16). The relative incidences of the facial clefts are given in Table 1-1.[30]

Common Cleft Lip and/or Cleft Palate

Common clefts of the lip and/or palate account for 98.8% of all facial clefts.[46] They may involve the lip only, the lip and palate, or the palate only, unilaterally or bilaterally. Approximately 50% to 70% of all cases of cleft lip/palate are nonsyndromic.[13] The rest are divided among more than 300 presently recognized entities.[13] Cleft lip (with or without cleft palate) should be recognized as an entity distinct from cleft palate only, but the two conditions are usually considered together in series of facial clefting.[47]

The nature and incidence of clefting vary among populations. Caucasians show nonsyndromic clefting of the lip and/or palate in 1 per 700 to 1000 live births.[48] Clefting of the palate alone (cleft palate only) occurs less fequently: 6.5 per 10,000 births.[48] In 460 patients with oral clefts in France, the lesion was an isolated cleft lip in 19.1%, combined cleft lip plus cleft palate in 37.2%, and cleft palate only in 43.7%.[49] Of the 171 infants with complete cleft lip and palate, the clefts were unilateral in 58.5% and bilateral in 41.5%.[49] Study of 1669 consecutive *surgically treated* cleft lips and cleft palates in Iran found that, in that group, isolated cleft lips were slightly more common in women

FIGURE 1-16 Facial clefting. Nonanatomic clefts in a 12-year-old mentally retarded girl with the syndrome of amnionic bands. Lateral view. A long, thin band-like scar extends across the scalp and face from the temporoparietal region through the cheek and the corner of the mouth to the lower lip. The large posterior zone of atrophic skin, absent hair, tissue bulging, and inferior displacement of the ear indicate the site of an associated temporoparietal encephalocele. Imaging studies showed notching and separation of teeth where the band crossed the alveolar ridge.

(1.16:1) and that combined cleft lip/cleft palate was significantly more common in men (2.2:1).[50] Cleft palate only was very slightly more common in women (1.1:1).[50] The combination of cleft lip plus cleft palate is more common than either isolated cleft lip or isolated cleft palate.[50] Both isolated cleft lip and combined cleft lip/cleft palate are more often unilateral than bilateral and affect the left side more than the right (Table 1-2).[50] Unilateral left-sided clefting, unilateral right-sided clefting, and bilateral clefting occur in a ratio of 6:2:3 (Table 1-2).[50] Table 1-3 summarizes a 50-year experience with 2297 clefting patients in Denmark.[47]

Pathogenesis of Cleft Lip/Cleft Palate and of Cleft Palate

Both genetics and environment have been implicated in facial clefting. The risk of a child's being born with a cleft lip and palate is 4% if one parent *or* one sibling is affected but 17% if both one parent *and* one sibling are affected.[51] This indicates a heritable component. Dietary supplementation with vitamins B_6 and folic acid during the first trimester markedly decreases the risk of recurrence in women who had previously borne children with cleft lip and palate.[48] This indicates a potential role for teratogens (or deficiencies). Teratogens linked to facial clefting include cortisone, anticonvulsants such as phenytoin, salicylates, aminopterin, organic solvents, maternal alcohol ingestion, maternal diabetes mellitus, maternal rubella, and the season of gestation. Increased maternal and paternal age may also play a role.[48] Maternal smoking during early pregnancy is a clear risk factor for cleft lip/palate. Study of 2207 pregnancies leading to cleft lip/palate showed a definite increase in the incidence of cleft lip/palate in children of mothers who smoked during pregnancy and an increasing risk of cleft lip/palate with increasing amounts of smoking.[52] The odds ratio for clefting increases from 1.32 for women who smoke 1 to 10 cigarettes daily to 1.69 for those who smoke 21 or more cigarettes daily.[52] Smoking seems to synergize with uncommon polymorphisms in the TGF-alpha gene at chromosome 2p13 to increase the risk of cleft palate sixfold.[2] Statistically significant elevations in lactate dehydrogenase and creatine phosphokinase have been reported in the amnionic fluid of human fetuses with cleft lip/cleft palate (vs. control normal fetuses).[53]

Genes and Heritability

Families of patients with cleft lip (with or without cleft palate) rarely include individuals with isolated cleft palate, and vice versa, probably because the primary and secondary palates form independently.[48] Nonsyndromic orofacial clefting (OFC) (cleft lip with or without cleft palate) has been mapped to genes designated *OFC1* at chromosome 6p23, *OFC2* at 2p13, interactions between *OFC1* and *OFC2*, and *OFC3* at 19q13.2.[48] Patients with OFC constitute a heterogeneous group, with some clefts inherited by autosomal dominance, others as a multifactorial threshhold trait, and still others by oligogenic inheritance.[48]

The gene products related to cleft lip and cleft palate have been characterized as TGF-alpha (2p13), retinoic acid receptor alpha (RARA) (17q21.1), MSX1 (4p16.1), and BCL3 (19q13.2).[48] In animals the gene *endothelin-1* lies in the OFC1 region at chromosome 6p23-24.[48] ''Knockout'' mice deficient in OFC1 show craniofacial malformations including cleft palate.[48] Mice deficient in endothelin converting enzyme-1 or in endothelin-A receptor show nearly identical malformations. END1, the transcription factor dHAND, and the gene *MSX1* (*Hox 7*) may form a signal cascade that regulates the development of neural crest–derived branchial arch mesenchyme.[48, 54, 55]

Nonsyndromic cleft palate only (CPO) has uncertain inheritance but may arise as a recessive single major locus

with low penetrance.[48] *TGF-β3* is a major candidate gene for mutation in human isolated cleft palate.[22] It is localized in a temporally and spatially restricted fashion in the medial edge epithelia of the fusing palate. Culture of palatal shelves in the presence of neutralizing antibody to *TGF-β3* or anti-sense oligonucleotides to *TGF-β3* prevents fusion of the palatal shelves.[56] *TGF-β3* knockout mice show isolated cleft palates extending from the posterior soft palate into the hard palate for a variable distance.[11] Cleft secondary palates are seen in knockout mice with deficiency of the GABA-producing enzyme glutamic acid decarboxylase and deficiency of the β-3 subunit of the $GABA_A$ receptor genes.[48] A different lesion would appear to explain the rare human X-linked cleft palate.[11]

Clinical Features

Children with cleft lip and palate face aesthetic and functional problems (Fig. 1-13). The extent of these difficulties depends on the type of cleft and its severity. Functionally, the cleft in the *palate* is most significant, because the palate is critical to achieving adequate intraoral suction for early feeding and to closing the nasopharynx (velopharyngeal valve) for later speech. Aesthetically, children with cleft lip with or without cleft primary palate face potential postoperative asymmetries of the lip and nose, visible scars, and either tissue deficiencies or excess. Functionally, they face potential dental and orthodontic problems related to the effect of the cleft on the alveolar-maxillary position and on dental development. Those with complete cleft lip and palate and those with isolated clefts of the secondary palate face problems with speech and language, including limitation of the phonemic repertoire, poor intelligibility, and delayed development of expressive and receptive language skills. The degree of delay is directly related to the adequacy and timing of palate repair.

Further problems relate to the growth of the midface, dental occlusion, and the effect of the clefting on eustachian tube function. The degree of later midface deformity depends on the initial distortion in facial development, the timing and type of surgical repair, and the integration of cleft care for all aspects of cleft palate management. Clefting causes concurrent abnormalities in development and orientation of the palatal muscles (particularly the levator palatini and tensor veli palatini). Abnormality in these muscles directly affects the function of the eustachian tube, the child's ability to aerate the middle ear, and the incidence of otitis media. Special attention must be directed to the potential for loss of hearing secondary to infection and to any additional impact that this complication would have on speech development.

Facial Deformities

Physical examination and imaging reveal structural changes in most areas of the face.

Lip

The clefts of the lip may be complete, incomplete, unilateral, or bilateral. Incomplete clefting, whether unilateral or bilateral, can occur in isolation or in combination with a complete clefting of the opposite side of the lip. The distortions in the soft tissues of the lip vary with the cleft and its severity. *Complete unilateral clefts* of the lip extend from the floor of the nostril, through the lip, to a point below the nostril (Fig. 1-17). The lip is shortened on both sides of the cleft, usually asymmetrically, with greater shortening on the medial side. The normal landmarks of the vermillion-

FIGURE 1-17 Unilateral cleft lip and palate in a 2-year-old boy. **A**, Three-dimensional CT of the skin surface. **B**, Three-dimensional CT of bone surface. **C**, Coronal CT. **D**, Axial CT. The unilateral cleft extends through the lip, the alveolar ridge, and the palate on the left. In this patient, the soft-tissue cleft lies lateral to the deformed ala nasi and extends toward the lacrimal sac fossa.

cutaneous junction and the vermillion-mucosal junction are distorted. The vermillion tapers upward along the cleft toward the nostril sill. There is a deficiency of vermillion on the medial side. The underlying muscle of the upper lip does not decussate in the midline of the lip, but streams parallel to the border of the cleft and inserts at the alar base. This altered course, failure of decussation, and concurrent distortion of the levator labii superioris create a ''fullness'' in the segment of the lip lateral to the cleft termed the orbicularis bulge. Patients with *incomplete unilateral cleft lips* show lesser degrees of vertical lip deficiency and muscle distortion proportional to the completeness of the cleft. There may be a small coloboma in the *lower* portion of the lip, a groove in the skin overlying the cleft, and absence of hair and sweat glands in the skin overlying the cleft.[57] Patients with *complete bilateral cleft lip* show similar disorganization of structure on both sides (Fig. 1-18). The central lip segment (prolabium) develops no underlying

FIGURE 1-18 Bilateral cleft lip and palate in a 2-month-old boy. **A**, Three-dimensional CT of the skin surface. **B**, Three-dimensional CT of bone surface. **C**, Coronal CT. **D**, Axial CT. **E**, Saggital T1 MRI. **F**, Axial T2 MRI. The symmetric clefts extend through the lips, the bases of the nostrils, the alveolar ridges, and the palate, leaving a distorted premaxillary segment with the central prolabium isolated from the paired maxillary processes. The prominent central incisors and smaller lateral incisors are positioned far anterior to the maxillary arches. The clefts course obliquely from anterolateral to posteromedial between the primary and secondary palates (cf. Fig. 1-5) before continuing directly posteriorly between the two maxillary palatal shelves to either side of the ununited septum.

Copyright © 2003, Mosby, Inc. All rights reserved.

muscle, only connective tissue. The degree of deficiency of prolabial tissue varies in width and vertical extent. Minimal vermillion is present. The labial sulcus is absent. The underlying premaxilla varies in position and may project forward or remain in reasonable alignment. The position of the premaxilla significantly affects the appearance and position of the prolabial segment of the lip.

Maxilla

In comparison to persons with normal palates, those with cleft palates show consistent but variable degrees of midfacial hypoplasia. The anterior hemimaxilla shows a narrowed curvature on the side of the cleft (''arch collapse'') and upward tilting of the premaxillary segment.[58, 59] The palatal (inferior) end of the nasal septum nearly always lies on the side of the cleft, while the anterior nasal spine of the maxilla nearly always lies on the noncleft side.[58, 59] This asymmetry probably arises as the tongue pushes into the cleft, and the divided lip and cheek muscles pull asymmetrically on the anterior nasal spine. The posterior maxillary arch is widened in patients with unilateral cleft lip and palate, but the vertical development of the posterior maxilla is normal.[58–62]

Nose

Unilateral Cleft On the cleft side, the angle between the medial and lateral crura is obtuse, the ala is caudally displaced, the alar-facial groove is absent, and the alar-facial attachment is at an obtuse angle. There is real or apparent bony deficiency of the maxilla. The circumference of the naris is greater. The naris is retrodisplaced. The columella is shorter in the anteroposterior dimension, and the medial crus is displaced.The nasal septum is typically deflected toward the cleft side, both superiorly and posteriorly, then deflects back toward the noncleft side, with the caudal septum presenting in the normal nostril. The bony pyramid is also deflected toward the cleft side, with varying deficiencies of the skeletal support for the nose due to the deficiency of the maxillary segment on the side of the cleft.

Bilateral Cleft The most visible feature of the bilateral cleft nose is shortening and deficiency of the columella centrally, with splaying and caudal displacement of the alar cartilages to both sides. These distortions create the typical blunted flat nose, widened nostrils, and displaced alar bases. The nasal septum may be midline or variably deflected, depending on whether the cleft is incomplete or asymmetric. Similarly, variations in the position of the smaller segments of the lips and the underlying hemimaxillae affect the degree of nasal widening and flattening.[57]

Concurrent Malformations

Malformations of other body parts occur in 7.73% (Iranian series) to 36.8% (French series) of patients with cleft lip and/or cleft palate.[49, 50, 63] Malformations are more common with isolated cleft palate (46.7%) than with combined cleft lip plus cleft palate (36.8%) or isolated cleft lip (13.6%).[49] An American series of 3804 cases confirmed that concurrent malformations were more common with isolated cleft palate (51.7%) than with cleft lip plus cleft palate (26.2%).[63] In the French series, infants with clefting showed concurrent chromosomal syndromes (7.8%), recognized nonchromosomal syndromes (3.3%), facial anomalies (11.1%), eye anomalies (2.6%), ear anomalies (1.1%), and diverse malformations of the central nervous system (8.5%), skeletal system (7.8%), urogenital system (6.3%), cardiovascular system (4.6%), digestive system (3.3%), abdominal wall (1.3%), skin (0.43%), and other regions (2.6%).[49]

Subtle Deformities in Parents of Patients with Common Clefts

Parents of children with cleft lip and palate show an increased incidence of facial asymmetry, wider bizygomatic distance and wider tragus-subnasal distance than do controls, and an increased incidence of nasal deformity and microform cleft lip.[51] However, parents of children with clefts show no divergence from the normal population in their occlusion or dentition.[57] Compared to parents of normal children, parents of children with unilateral clefts show no asymmetry in tooth size and no difference in the incisor relationship, overjet, overbite, and intercanine widths.[57] Parents of children with unilateral and bilateral clefts display equal tooth number, tooth width, and intercanine widths.[57]

Midline Cleft Lip and Median Cleft Face Syndromes

Median cleft lip is a rare anomaly related to midline craniofacial-cerebral dysraphism.[46] In Fogh-Andersen's series of 3988 craniofacial clefts collected over 30 years (Table 1-1), median clefts of the upper lip were observed in only 15 cases (0.38).[46] Five (0.13%) were true median cleft lips (as considered here) (Fig. 1-12B), three more (0.08%) were true medial cleft lips occurring as part of the orofacial digital syndrome (Fig. 1-12C,D), and seven (0.17%) were pseudomedian cleft lips. An additional four (0.10%) were cases of median cleft nose. Nearly all cases of median cleft face syndrome occur sporadically.[64, 65] Only a few familial cases have been reported.[44, 66–68] An unexpectedly high 12% to 18% of patients with median cleft face syndrome are the products of twin gestation,[44, 66, 67] but the other twin is usually normal. Focal neurologic deficits are not reported with median cleft face syndrome[66, 67, 69–78] and do not appear to form part of the disease. These patients have variable intellectual development. Patient IQ does not appear to be related to the severity of facial clefting.

The midline craniofacial dysraphisms fall naturally into two groups: (A) an inferior group in which the clefting primarily involves the upper lip (with or without the nose) and (B) a superior group in which the clefting primarily affects the nose (with or without the forehead and upper lip). Group A is associated with basal encephaloceles, callosal agenesis (rarely lipoma), and optic nerve dysplasias such as optic pits, colobomas, megalopapilla, persistent hyperplastic primary vitreous with hyaloid artery, and morning glory syndrome (Figs. 1-19 and 1-20). Group B consists of patients with the median cleft face syndrome. This group is characterized by hypertelorism, a broad nasal root, and a median cleft nose (with or without median cleft upper lip, median cleft premaxilla, and cranium bifidum occultum frontalis).[66, 69] Group B patients manifest an increased incidence of

dysplasia (Figs. 1-12B, 1-19, and 1-20). The labial defect observed varies from a small notch, to a vertical linear cleft, to a small triangular deficiency of the midline upper lip vermillion (with or without philtrum), with absence of the labial tubercle. This defect is designated *true midline cleft upper lip*. Rarely, this defect may also occur as an isolated finding or as part of the orofacial digital syndromes I and II (Fig. 1-12C,D).[79–81]

Patients with median cleft upper lip may show basal encephaloceles, rare anomalies estimated to constitute

1.2% of all encephaloceles (Figs. 1-12B, 1-19, and 1-20).[82, 101–104] Table 1-4 summarizes the findings in a total of 30 cases collected from the literature and personal material.[43, 66, 83–100] In this series, 50% manifested midline cleft lip (but not nose), an additional 13% manifested agenesis, and 40% manifested optic nerve dysplasia (i.e., any of the spectrum of optic pit, optic/perioptic coloboma, morning glory disc, and/or megalopapilla). Since the reports are incomplete in many cases, the true concurrence of these anomalies is likely to be even higher.

To date, no report details the true incidence of encephalocele, callosal agenesis, and facial clefting in patients with optic nerve dysplasias.[90–93, 105–109] However, Beyer et al.[110] found one sphenoidal encephalocele in eight patients with 10 morning glory discs, a single-series incidence of 10% to 15%. Lipoma of the corpus callosum is observed in approximately 0.06% of all patients in both in vivo and necropsy studies.[111] Agenesis of the corpus callosum is present in 35% to 50% of such cases.[111] Midline interhemispheric lipoma may be associated with midline subcutaneous lipomas, cranium bifidum, and frontonasal encephaloceles.[66, 112, 113]

Group B

Median cleft face syndrome (frontonasal dysplasia) is a rare form of dysraphism that affects the midface (Figs. 1-21 and 1-22). The characteristic physical findings in median cleft face syndrome include hypertelorism, cranium bifidum occultum frontalis, widow's peak hairline, and midline clefting of the nose (with or without cleft upper lip, premaxilla, and palate).[44, 66, 69, 114–116] There may also be common clefts of the upper lip and palate, primary telecanthus, ocular colobomas, microphthalmia, and notching of the alae nasae. Hypertelorism is present in all cases of median cleft face syndrome and is the one *obligatory* finding.[69] The next most constant finding is true midline bony clefting of the nose. The other facial deformities may be present or absent in varying degree.

The types of facial clefting seen in this syndrome have been classified differently by different authors.[64, 66, 69] DeMyer classified the median cleft face syndrome into four classical facies, which represent the most frequently encountered combinations of the major and minor defects of median cleft face syndrome (Table 1-5).[64, 66] Sedano et al.[69] proposed an alternative classification of median cleft face syndrome (Table 1-6). These systems differ, in part, in the importance attributed to notching of the alae nasae (Table 1-7). In our opinion, the Sedano et al. classification appears to correlate best with the intracranial pathology and is the most useful system.

Molecular Genetics

In mice, severe nasal clefting results from defects in the aristaless-related genes (*Alx3* and *Alx4*), which are upstream regulators of *sonic hedgehog*.[117] Mice with the compound null mutation *Alx3/Alx4* show severe midline clefts of the nose with malformation, truncation, or absence of most of the facial bones, skull base, and other elements derived from neural crest.[117] There is significantly increased apoptosis localized to the outgrowing frontonasal process at (mouse) embryonic day (ED) 10.0, leading to an abnormal position of the nasal processes when they appear at ED 10.5.[117] Thereafter, failure of the medial nasal processes to fuse in the midline leaves defects ranging in severity from partial splitting of the nasal tip to wide separation and anterior truncation of the lateral halves of the nose.[117] The nasal capsule may form as two separate halves, each closed by a

Compound null *Alx3/Alx4* mice also show severe reduction in the frontal and parietal bones, with widened fontanelles.[117]

Concurrent Malformations

Median cleft face syndrome has been found to coexist with many other syndromes.[44, 67, 68, 70–78, 113, 114, 118–125] One review of 11 cases of median cleft face syndrome found 3 type A facies, 4 type B, 4 type D, and no type C. Hypertelorism and a broad nasal root were found in 100% (by definition), true midline bony cleft of the nose in 8 of 11 (all cases except type A facies), median cleft upper lip in 3 of 11, common cleft lip in 3 of 11, common cleft palate in 3 of 11, cranium bifidum in 6 of 11, calcified falx in 6 of 11, interhemispheric lipoma in 5 of 11, Gorlin-Goldenhar syndrome in 2 of 11, and twinning in 2 of 11 patients.[44] We have also seen one patient with concurrent Kallmann syndrome, midline facial cleft, and hypotelorism.[126, 127]

The imaging features of median cleft face syndrome include hypertelorism, cranium bifidum, facial clefting, and intracranial calcifications related to interhemispheric lipoma and/or calcification of the anterior aspect of the falx (Fig. 1-22).[44, 123, 126, 127] The calcification of the falx produces a thick frontal crest that is most commonly found when a lipoma is present, but may be present without associated lipoma.[114]

Transverse Facial Clefts

Transverse facial clefts represent failure of the maxillary and mandibular processes to form the corner of the mouth and the cheek (Fig. 1–15).[45] (These are discussed in greater detail in the section on Hemifacial Microsomia.)

Clefts of the Lower Lip and Mandible

Median clefts of the lower lip and the mandible are rare in humans. They vary widely from a simple notch of the vermillion to a complete cleft of the lower lip involving the tongue, the chin, the mandible, the supporting structures of the median of the neck, the hyoid, and the manubrium sterni.[128] The anterior tongue is often bifid (rarely absent). It may be bound to the divided mandible (ankyloglos-

Copyright © 2003, Mosby, Inc. All rights reserved.

sia).[128, 129] The hyoid bone may be cleft or absent.[128] The clefting of the neck may be accompanied by cysts, chords, contractures, and even midline dermoids of the neck.[128, 129] These lower midline clefts may also be associated with midline clefting of the upper lip and nose.[129]

Cleft lower lip, mandible, and neck may result from mutations in upstream regulators of *sonic hedgehog* (e.g., the aristless-like homeobox genes *Prx1* and *Prx2*) that control cell proliferation during morphogenesis. *Prx1* and *Prx2* mutant mice show reduced size or absence of the midline mandible, an absent or single mandibular incisor, and reduction in their limbs. The mandibular features are consistent with reduced lateral expansion of the medial elements of the jaw. Treatment with the plant alkaloid jervine inhibits end organ response to sonic hedgehog and produces very similar phenotypes in the treated mice.[15, 117]

Syndrome of Amniotic Bands

Rupture of the amnion can precipitate a cascade of secondary events collectively designated the *amniotic band disruption complex*.[130] In this complex, bands of amnion may interrupt normal morphogenesis, crowd fetal parts, or actually disrupt previously formed parts.[130] Facial clefts may then result from a strand of amnion situated between and preventing the expected fusion of two facial processes, or from a strand of amnion that cleaves through a region not normally formed by fusion, leading to nonanatomic facial clefts and encephaloceles (Fig. 1-16).[130] The frequency and extent of such malformations are greater when the disruption occurs earlier in pregnancy.[130] In 33 cases of this syndrome wherein the timing of the amniotic rupture could be estimated, facial clefts were found in 96% of cases when the rupture occurred prior to 45 days' gestation but in no case in which the rupture occurred after 45 days.[130] Severe defects in the central nervous system and the calvarium such as anencephaly, cephalocele, and hydrocephalus were also common (88%) when the amnion ruptured before 45 days' gestation and were not seen thereafter.[130]

NASAL DERMAL SINUSES, CYSTS, HETEROTOPIAS, AND CEPHALOCELES

In the early embryo, the developing frontal bones are separated from the developing nasal bones by a small fontanelle called the fonticulus frontonasalis.[131–133] The nasal bones are separated from the subjacent cartilaginous nasal capsule by the prenasal space (Figs. 1-23 and 1-24). This space extends from the base of the brain to the nasal tip.[132] Midline diverticula of dura normally project *anteriorly* into the fonticulus frontonasalis and *anteroinferiorly* into the prenasal space. These diverticula touch the ectoderm. Normally, the diverticula regress prior to the closure of the bone plates of the anterior skull base. Normally, the fonticulus frontonasalis is closed by union of the nasal bones with the nasal processes of the frontal bone to make the frontonasal suture.[134] The prenasal space becomes obliterated as the cartilaginous nasal capsule develops into the upper lateral nasal cartilages and the

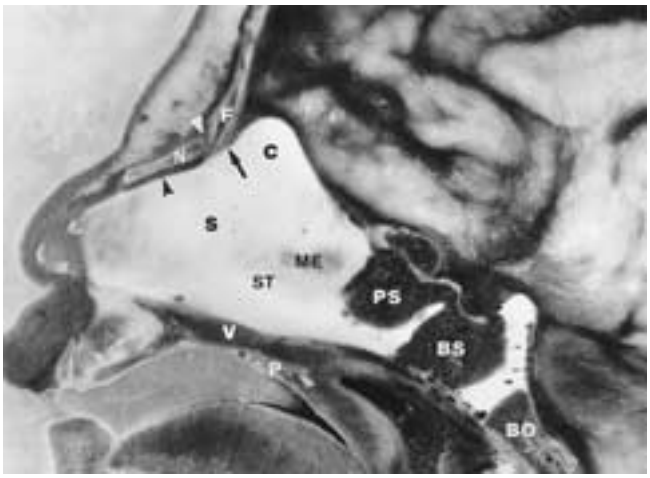

FIGURE 1-23 Midsagittal cryomicrotome section of a full-term newborn demonstrates the normal relationships at birth among the ossified frontal bone (*F*), the ossified nasal bone (*N*), the frontonasal suture (*white arrowhead*), and the cartilaginous nasal capsule (*large white structure*) that forms the still-unossified nasal septum (*S*) and crista galli (*C*). The ossified hard palate (*P*) and ossified vomer (*V*) lie below the septal cartilage. Note the direct line from the prenasal space (*black arrowhead*) through the foramen cecum (*black arrow*) to the normal depression or ''fossa'' just anterior to the crista galli. The midline septal cartilage is directly continuous with the cartilaginous skull base. The basioccipital (*BO*), basisphenoidal (*BS*), and presphenoidal (*PS*) ossification centers are well formed. The mesethmoidal (*ME*) ossification center is just beginning to form. When the vomer and mesethmoid enlarge, the residual cartilage between them is designated the sphenoidal tail (*ST*).

VIEW IMAGE

ethmoid bone including the crista galli, cribriform plates, and perpendicular plate of the septum.[132] The two leaves of the falx normally insert into the crista galli, one leaf passing to each side of the crista. At the skull base, the frontal and ethmoid bones close together around a strand of dura, leaving a small ostium designated the foramen cecum. Normally, this transmits a small vein. This foramen is easily

VIEW IMAGE

FIGURE 1-25 Diagram of a typical nasal dermal sinus and cyst traversing the prenasal space and the enlarged foramen cecum to form a mass anterior to and within a groove in the anterior concavity of the crista galli. *Inset*: The anatomic relationships of the leaves of the falx to the sides of the crista galli direct upward extension of the mass into the interdural space between the leaves of the falx. (From Gorenstein A, Kern EB, Facer GW, et al. Nasal gliomas. Arch Otolaryngol 1980;106:536.)

seen at the bottom of a small depression that lies just in front of the crista galli. It is not certain whether the foramen is situated exactly at the frontoethmoidal junction or between the nasal processes of the frontal bones.[132]

If the embryonic diverticula of dura become adherent to the superficial ectoderm, they may not regress normally. Instead, they may pull ectoderm with them as they retreat, creating an (ecto)dermal tract that extends from the glabella through a canal at the frontonasal suture to the crista galli or beyond the crista to the interdural space between the two leaves of the falx.[131, 132, 135] A similar persistent tract may pass from the external surface of the nose, under or through the nasal bones, and ascend through the prenasal space to enter the cranial cavity at the foramen cecum just anterior to the crista galli (Fig. 1-25). Such a tract would be associated with a widened foramen cecum, distortion and grooving of the crista galli, and extension into the interdural space between the two leaves of the falx. Depending on the precise histology of the portions of the tract that persist, these tracts could develop into superficial glabellar and nasal pits, fully patent glabellar and nasal dermal sinuses, and/or one or several (epi)dermoid cysts and/or fibrous cords. Rarely, the sinus tracts, cysts, and cords may extend into or become adherent to the brain itself.[136] Nasal cephaloceles and gliomas may arise by an analogous mechanism. Indeed, there are no valid *histologic* criteria to differentiate between the two entities.[137] If the dural diverticulum persists as a patent communication that contains leptomeninges, CSF and neural tissue, that state would constitute a glabellar or nasal meningoencephalocele (Fig. 1-26). If the developing structure becomes ''pinched off'' and (nearly) isolated from the cranial cavity by subsequent constriction of the dura and bone, it constitutes a heterotopic focus of meninges and neural tissue at the glabella and nose. Such a benign, nonneoplastic glial heterotopia is given the dreadful misnomer glabellar and nasal glioma (Fig. 1-27).

Dermoids and Dermal Sinuses

Dermoids of the Skull

Dermoids of the skull occur at sites related to the closure of the neural tube, the diverticulation of the cerebral hemispheres, and the lines of closure of the cranial sutures (Fig. 1-28). Pannell et al.[138] classified 94 dermoids of the skull into three groups: A. *Midline dermoids* (43%) affect the anterior fontanelle (25), glabella (1), nasion (2), vertex (1), and the occipital/suboccipital region (11). B. *Frontotemporal dermoids* (45%) affect the sphenofrontal (15), frontozygomatic (16), and sphenosquamosal (11) sutures. C. *Parietal dermoids* (13%) affect the squamosal (8), coronal (1), lambdoid (1), and parietomastoid (2) sutures. Bartlett et al.[139] categorized 84 orbitofacial dermoids into three slightly different groups. In this classification: A. *Frontotemporal dermoids* (64%) are single, slowly growing, asymptomatic lesions ranging from a few millimeters to several centimeters in size. They cluster about the eyebrows, are equally frequent on the left and right sides,

and show a slight female preponderance. None extends intracranially. B. *Orbital dermoids* (25%) are single lesions of variable size, are equally frequent on the left and right sides, and are more common lateral to the midaxis of the globe (two thirds) than medial to the midaxis of the globe (one third). Thirty percent of the orbital dermoids adhere to the orbital wall: 20% at the frontozygomatic suture laterally or the confluence of the sutures medially, and 10% away from the sutures. Females predominate in this group (2:1). C. *Nasoglabellar dermoids* (11%) are equally frequent on the left and right sides and equally frequent in males and females.[139]

Nasal Dermal Sinuses

Nasal dermal sinuses are thin (1-3 mm) epithelium-lined tubes[140] that (1) arise at external ostia situated along the midline of the nose and (2) extend deeply for a variable distance, sometimes reaching the intradural intracranial space. *Nasal dermoid and epidermoid cysts* are midline epithelium-lined cysts that arise along the expected course of the dermal sinus. They may coexist with dermal sinuses or present as isolated masses (Table 1-8[142]; Figs. 1-29 and 1-30). Nasal dermal cysts and sinuses constitute 3.7% to 12.6% of all dermal cysts of the head and neck and 1.1% of all such cysts throughout the body.[131, 140] There is no sex predilection.[131, 141–143] They may occur in isolation, as one of a small number of concurrent malformations, or as part of well-known syndromes, including hemifacial microsomia, frontonasal dysplasia, oro-facial-digital syndrome type I, and the *v*ertebral defects, imperforate *a*nus, *t*racheo*e*sophageal fistula, and *r*adial and *r*enal dysplasia (VATER) association.[144] Familial cases are known but rare.[144–146]

Nasal Dermoids and Epidermoids

Nasal dermoids and epidermoids cluster in three areas: the midline just superior to the nasal tip, the junction of the upper and lower lateral cartilages, and near the medial canthus. Glabellar cysts external to the frontal bone

are less common (Figs. 1-31 and 1-32). True epidermoids occur as often as true dermoids, but epidermoids are more common at the glabella-nasion, whereas dermoids are more common along the bridge of the nose (Figs. 1-33 and 1-34).[141] On occasion, multiple sinus ostia are present or sinuses and cysts coexist at both the glabella and the nasal bridge.[131, 147]

Nasal dermal sinuses and cysts are usually detected early in life (mean age, 3 years) as midline nasal cysts (56%) or midline pits (44%), which may contain sparse wiry hairs (Table 1-8) (Figs. 1-35 and 1-36).[142, 148, 149] There may be intermittent discharge of sebaceous material and/or pus; intermittent inflammation; increasing size of the mass with variable degrees of broadening of the nasal root and bridge; intermittent episodes of meningitis; or behavioral change secondary to a frontal lobe abscess (Table 1-8).[142] The sinus ostium may be ''pinpoint'' and undetectable until pressure is applied against the nose to express cheesy material.[131] Nasal dermal cysts may be soft and discrete or indurated. They may erode through the overlying skin to form secondary sinus pits. True epidermoids are seven times more likely than dermoids to become infected.[141] Together, nasal dermal sinuses and cysts account for approximately 5% of the intracranial abscesses found in relation to all types of nasal, sinus, and orbital infections.[150]

Nasal dermal sinuses open at any site from the glabella downward along the bridge (dorsum) of the nose to the base of the columella.[151] In one family of identical triplets, each child had a nasal dermal sinus, but the ostia lay at three different sites (nasion, bridge, and tip).[144] Overall, the

When the sinus ostium (*arrow*) lies at the base of the columella, extension to the intracranial space is rare.

VIEW IMAGE

external ostium of the sinus is found at the glabella-nasion in 25%, the bridge of the nose in 31%, the nasal tip in 19%, and the base of the columella in 25% (Table 1-9).[148]

The depth to which nasal dermal sinuses and cysts extend is highly variable. The lesions can be shallow pits that end blindly in the superficial tissue (Fig. 1-30C) or long tubes that wander extensively extra- and intracranially (Figs. 1-36 and 1-37).[131] In Bradley's review of 67 children with nasal dermoids, the lesion was confined to the skin in 61% and extended deeply to invade the nasal bones in 10%. The lesion extended into the septal cartilage in 10%, the nasal bones and cartilage in 6%, and the cribriform plate in 12%.[141] Rare sinuses may traverse the entire anteroposterior extent of the nasal septum to end at the basisphenoid, where they attach to the dura just anterior to the sella.[131] Intracranial extension of the dermal sinus is more frequent in patients with multiple anomaly syndromes (67%) than in those with isolated nasal dermal sinuses (31%).[144] The location of the sinus ostium does *not* predict whether there is any intracranial extension. Intracranial extension can be associated with cysts and sinuses at *nearly* any site, but the frequency of such extension does change with sinus location (Table 1-9).[142] In Pensler et al.'s series,[142] each of four sinuses situated at the base of the columella passed directly to the nasal spine of the maxilla, with no intracranial extension. However, Muhlbauer and Dittmar[145] report a similar sinus that ascended to end in the ethmoid air cells; it did not enter the cranial cavity.

The intracranial end of (epi)dermoids usually affects the anterior epidural space near the crista galli, and from there may pass deeper, between the two leaves of the falx, as an *inter*dural mass.[142, 144] Rare lesions also extend into the brain.[136] In approximately 31% of cases with intracranial extension, the tissue extending inward is a fibrous cord devoid of (epi)dermal elements. At present, intracranial extension of a fibrous cord is not considered significant and has not been associated with sequelae on follow-up examination.[142]

Nasal dermal sinuses are resected for three major reasons: for cosmesis, to avoid/treat complications of local

Copyright © 2003, Mosby, Inc. All rights reserved.

infection, and to avoid/treat secondary meningitis and cerebral abscess (Fig. 1-38).[151] Late development of squamous cell carcinoma has not been observed with *nasal* dermal sinuses to date.

Imaging studies successfully display the course of sinus tracts and any sequelae of infection. The ostium and tract usually appear as isodense fibrous channels or as lucent dermoid channels that extend inward for a variable distance. Bony canals indicate the course of the sinus through the nasal bones, ossified nasal septum, and skull base (Fig.

1-32). An uncomplicated dermoid cyst appears as a well-defined lucency/signal with a sharply marginated capsule (Figs. 1-31 to 1-33). Swelling and edema around the cyst suggest secondary inflammation (Fig. 1-34).[152] The intracranial ends of dermoid cysts typically lie in a hollowed-out gully along the anterior surface of a thickened, enlarged crista.[131] This hollow gives a false impression of a *bifid* crista.[131] The intracranial portion of the dermoid may be lucent or dense. Unfortunately, the only proof of intracranial extension is actual demonstration of an intracranial mass. Imaging demonstration of an enlarged foramen cecum and distorted crista galli only *suggests* such extension; it does not prove it. Foraminal enlargement and distortion of the crista seem to form part of the malformation and may be present (1) with intracranial extension, (2) without intracranial extension, or (3) with intracranial extension of a *fibrous* cord rather than a dermoid.[142] In our own series of 32 cases,[142] the foramen cecum was wide and the crista was grooved anteriorly (bifid) in 6 of 6 cases (100%) with intracranial extension. However, the foramen

FIGURE 1-35 Nasal dermal sinus with intracranial extension. **A**, Frontal view of a 1-year-old girl shows a small tuft of hairs protruding from a midline dermal sinus on the dorsum of the nose. **B**, Direct coronal CT. A well-marginated canal penetrates between the nasal processes of the frontal bones. **C**, Axial CT scan reveals a large foramen cecum with anterior grooving of the crista galli. At surgery the dermal sinus tract and extranasal dermoid were traced upward through the foramen cecum into a 2 to 3 cm intracranial dermoid. This extended intradurally but did not attach to brain. A second ''arm'' of the intranasal dermoid passed posteriorly toward the sphenoid bone.

cecum was also wide in 10 of 26 cases (38%) with no intracranial extension, and the crista was grooved anteriorly in 7 of those 10 cases. To avoid unnecessary craniotomies, therefore, surgical studies suggest that the best approach is to dissect the extracranial portion of the tract along its entire length from the superficial ostium to the *extra*cranial surface of the enlarged foramen cecum, to sever the tract at the extracranial end of the foramen cecum, and then to send the severed end for pathologic examination. If the specimen shows (epi)dermal elements at the foramen cecum, the dissection is extended intracranially. If no (epi)dermal elements are found at the foramen cecum and if no mass is shown by imaging studies, the procedure is concluded without intracranial exploration.[131, 142]

Heterotopic Brain Tissue

Nasal Heterotopias (Gliomas)

Nasal gliomas are congenital masses of glial tissue that occur intranasally and/or extranasally at or near the root of the nose. They may or may not be connected to the brain by a pedicle of glial tissue. By definition, they do not contain any CSF-filled space that is connected with either the ventricles or the subarachnoid space of the head.[153]

Nasal gliomas and cephaloceles form a spectrum of related diseases (Figs. 1-23 to 1-27). Characteristic encephaloceles contain ependyma-lined ventricles filled with CSF. Prototypical nasal gliomas consist of solid masses of glial tissue that are entirely separate from the brain.[153] Transitional forms include solid lesions with *microscopic* ependyma-lined canals, solid lesions intimately attached to the brain by glial pedicles with no ependyma-lined spaces, and solid lesions attached to the dura by fibrous bands with no glial pedicles.[153] Analysis of cases reveals that the presence or absence of a pedicle and the presence or absence of *thin* ependyma-lined channels are not helpful in making surgically and radiologically useful distinctions among these lesions. Thus the medically significant differential diagnosis between nasal gliomas and encephaloceles depends on the presence (encephalocele) or absence (nasal glioma) of communication between the intracranial CSF and any fluid spaces within or surrounding the mass.[154, 155] Indeed, nasal gliomas remain connected with intracranial structures in 15% of cases, usually through a defect in or near the cribriform plate.[132]

Nasal gliomas are uncommon, accounting for only 4.5% of congenital nasal masses.[131, 156] They occur sporadically, with no familial tendency.[132] They usually affect both genders equally,[132] although a 3:1 male preponderance has been reported.[156] Up to 15% of patients with nasal heterotopias also manifest multiple cerebral heterotopias.[137] Other congenital malformations of the brain or body are

rare. Nasal gliomas are subclassified into extranasal, intranasal, and mixed forms (Fig. 1-27).[132, 157]

Extranasal gliomas (60%) lie external to the nasal bones and nasal cavities.[137, 157] They typically occur at the bridge of the nose, to the left or right of the midline, but, curiously, not in the midline itself. Extranasal gliomas may also be found close to the inner canthus, at the junction of the bony and cartilaginous portions of the nose, or between the frontal, nasal, ethmoid, and lacrimal bones. They may extend into the maxillary antrum between the lateral edge of the nasal bone and the nasal cartilage.[158] Clinically, extranasal gliomas present in early infancy or childhood as

firm, slightly elastic, reddish to bluish, skin-covered masses. Capillary telangiectasias may cover the lesion. They are typically unilateral, most frequently on the right, and are rarely bilateral.[156] Nasal gliomas exhibit no pulsations, do not increase in size with the Valsalva maneuver (crying), and do not pulsate or swell following compression of the ipsilateral jugular vein (negative Fürstenburg sign).[132, 149, 155, 159–161] These lesions usually grow slowly in proportion to adjacent tissue but may grow more or less rapidly.[132] They can cause severe deformity by displacing the nasal skeleton, the adjoining maxilla, and the orbital walls, potentially causing hypertelorism.[132]

Intranasal gliomas (14% to 30%) lie within the nasal or nasopharyngeal cavities (Figs. 1-29, 1-39).[137, 157] Intranasal gliomas usually present as large, firm, polypoid, submucosal masses that may extend inferiorly toward or nearly to the nostril.[132, 160] They may protrude through the nostril secondarily.[159] They usually attach to the turbinates and come to lie medial to the middle turbinate, between the middle turbinate and the nasal septum.[132] Rarely, they attach to the septum itself. They expand the nasal fossa, widen the nasal bridge, and deviate the septum contralaterally. Obstruction of the nasal passage may lead to respiratory distress, especially in infants. Blockage of the nasolacrimal duct may cause epiphora on the affected side. CSF rhinorrhea, meningitis, and epistaxis may be the presenting complaints. Intranasal gliomas are commonly confused with inflammatory polyps. However, nasal gliomas usually have a firmer consistency and appear less translucent than inflammatory polyps.[127, 153] Intranasal gliomas typically lie medial to the middle turbinate, whereas inflammatory polyps typically lie inferolateral to the middle turbinate. Only posterior ethmoid polyps project into the same space as the nasal glioma. As an additional criterion, nasal gliomas

VIEW IMAGE

FIGURE 1-40 Mixed extranasal-intranasal glioma in an 8-month-old boy with a nasal mass that was present at birth and grew in proportion to the child. **A**, View of the face demonstrates a 3 by 3 by 3 cm firm left paramedian subcutaneous mass that displaces the septal and alar cartilage, narrowing the nostril. The mass did not pulsate or change size with crying. **B** and **C**, At surgery the mass was not bound to the subcutaneous tissue. It lay almost entirely external to the nasal bones, to the left of midline. A narrow stalk (*arrows*) passed directly through the left nasal bone and extended upward to the left cribriform plate. **D**, Bisecting the specimen revealed a homogeneous mass of smooth grayish-white shiny tissue. Histologic examination revealed brain and fibrous tissue consistent with nasal glioma.

typically present in infancy, whereas ordinary nasal polyps are exceptionally rare under 5 years of age.[161]

Mixed nasal gliomas (10% to 14%) consist of extranasal and intranasal components that communicate via a defect in the nasal bones or around the lateral edges of the nasal bones (Figs. 1-40 to 1-42).[137, 157] Rarely, these two portions communicate through defects in the orbital plate of the frontal bone or the frontal sinus. When *extra*nasal gliomas lie on *both* sides of the nasal bridge, the two components communicate with each other via a defect in the nasal bones, constituting a mixed nasal glioma.[155]

Histologically, nasal gliomas resemble reactive gliosis rather than neoplasia.[161] They consist of large aggregates or small islands of glial tissue with evenly spaced fibrous or gemistocytic astrocytes within vascularized fibrous tissue.[137, 158] The astrocytes may be multinuclear, but they exhibit no mitotic figures and no bizarre nuclear forms.[160] Fibrous connective tissue enwraps the blood vessels and extends outward to form collagenous septa that partially subdivide the mass.[160] Prominent zones of granulation tissue may be present.[160] The lesion is usually not encapsulated, but astrocytic processes, fibroblasts, and collagen may form a loose or dense connective tissue capsule.[132, 160, 162] *Extra*nasal gliomas are surrounded by dermis with dermal appendages.[132] *Intra*nasal gliomas are surrounded by minor salivary glands, fibrovascular tissue, and nasal mucosa.[132] Only 10% of reported nasal gliomas contain neurons.[160] Occasional lesions show distinct laminated ''cortical'' architecture, with an external acellular zone resembling the molecular layer of the cortex and an inner, more cellular zone.[137] Still other lesions have zones suggesting a pial layer around the glial tissue.[137] Calcification is rare.[153] Invasion

FIGURE 1-41 Mixed extranasal-intranasal glioma in a 6-month-old boy. **A**, Facies. The globular mass overlies the dorsum of the nose on the left. **B**, At surgery the lesion was found to have extended through the left nasal bones, bowed the septum (*S*) rightward, and bowed the residual left nasal bones (*N*) leftward. It was attached by a pedicle to the foramen cecum. **C** and **D**, Coronal and axial CT scans show that the mass extends through the resultant defect into the thickened nasal septum (*white arrowhead* in **D**). The crista galli and brain were normal. (Courtesy of Dr. Sharon Byrd, Chicago.)

of surrounding tissue has never been observed, and no metastases have been reported.[162] Thus, these lesions are classified as glial heterotopias, not neoplasias.[161, 163]

Nonnasal Heterotopias

Heterotopic brain tissue has also been identified at numerous nonnasal sites, including the orbit, hard palate, soft palate, nasopharynx, pterygopalatine fossa, tongue, upper lip, neck, and even lung.[164–170] These heterotopias may be grouped with the nasal gliomas but are probably better considered separately. Both nasal gliomas and nonnasal heterotopias contain glial cells within a fibrous matrix, but the nonnasal brain heterotopias typically show more advanced maturation and differentiation into neural components such as choroid plexus, ependyma-like epithelium, Nissl substance, and rare ganglion cells.[170] Nonnasal heterotopias are usually benign lesions. Solid lesions typically grow in proportion to the body. Cystic lesions may enlarge disproportionately rapidly, especially if they contain functioning choroid plexus.[170–172] Rarely, tumors have been reported in association with nonnasal heterotopias. Bossen and Hudson[173] reported a small oligodendroglioma arising within heterotopic brain tissue in the soft palate and nasopharynx. Lee et al.[174] reported a melanotic neuroectodermal tumor (melanotic progonoma) within an oropharyngeal mass of brain tissue.

Cleft palates have been reported in 6 of 17 patients (35%) with nasopharyngeal brain heterotopias.[175] Other nasopharyngeal lesions such as teratoid tumors, epignathi, dermoids, hairy polyps, and lipomas have also been associated with clefting of the soft palate.[176] It is unclear whether these concurrences reflect mechanical impediments to the formation of the palate or a midline ''clefting/twinning'' derangement of molecular signaling.

Epignathus Teratoma

Epignathus teratomas are congenital teratomas of the oropharynx found in 1 per 35,000 (up to 1 per 800,000) live births.[177] They occur sporadically, are more frequent in girls (female : male ratio = 3 : 1), and are more frequent in children of younger mothers.[177] Fetal history may disclose an elevated alpha-fetoprotein level and polyhydramnios due to

Copyright © 2003, Mosby, Inc. All rights reserved.

fetal difficulty with swallowing in utero.[177] These tumors are typically single masses attached to the skull base in the midline of the posterior nasopharynx, close to Rathke's pouch and the craniopharyngeal canal.[177] Infrequently, they may be multiple and/or may arise laterally.[177] Small epignathus teratomas are frequently pediculated and vary in position. Large tumors may extend intracranially via the craniopharyngeal canal, extend inferiorly to involve the hard palate, fill the oral cavity, deform the maxilla, and even protrude from the oral cavity.[177] Epignathus lesions are regarded as mature teratomas that do not recur after complete resection.[177] Malignant degeneration has not been described, but intracranial extension is often fatal.[177] Six percent of epignathus teratomas are associated with other malformations, most frequently cleft palate of mechanical origin.[177] Other concurrent malformations include duplicate pituitary glands, bifid noses, bifid tongues, and glossoptosis.[177] In the literature, five of seven patients with duplicate pituitary glands (71%) had concurrent epignathus teratomas, with or without callosal agenesis.[177]

Epulis

Congenital epulis is a rare tumor that affects the gingiva of infants.[178] The lesions may be single or multiple, are eight times more common in girls than in boys, and are three times more common in the maxilla than in the mandible.[178, 179] Epulides are usually not associated with malformations of the teeth, but hypoplasia or absence of the underlying tooth is seen occasionally.[178] Pathologically, the lesion is composed of large cells with eosinophilic granular cytoplasm within a vascular fibrous connective tissue.[178, 180] Electron microscopy shows that the tumor cells are filled with autophagosomes containing collagen precursors. Immunohistochemical stains are positive for vimentin and neuron specific enolase. These features suggest that epulis may arise from early mesodermal cells that express pericytic and myofibroblastic features, and which undergo cytoplasmic autophagocytosis.[180] Epulis may resolve spontaneously or require resection.[181] The lesions do not recur after resection and show no malignant potential.[178, 182]

Cephaloceles

Cephaloceles are congenital herniations of intracranial contents through a cranial defect.[183] When the herniation contains only meninges, it is designated a *cranial meningocele*. If the herniation also contains brain, it is called a *meningoencephalocele*. Cephaloceles are classified by the site of the cranial defect through which the brain and meninges protrude.[183, 190]

Sincipital Cephaloceles

Sincipital cephaloceles are cephaloceles situated in the anterior part of the skull.[161, 184–191] These include both interfrontal cephaloceles (Fig. 1-43) and frontoethmoidal cephaloceles (Figs. 1-44 to 1-49).[161] Sincipital cephaloceles

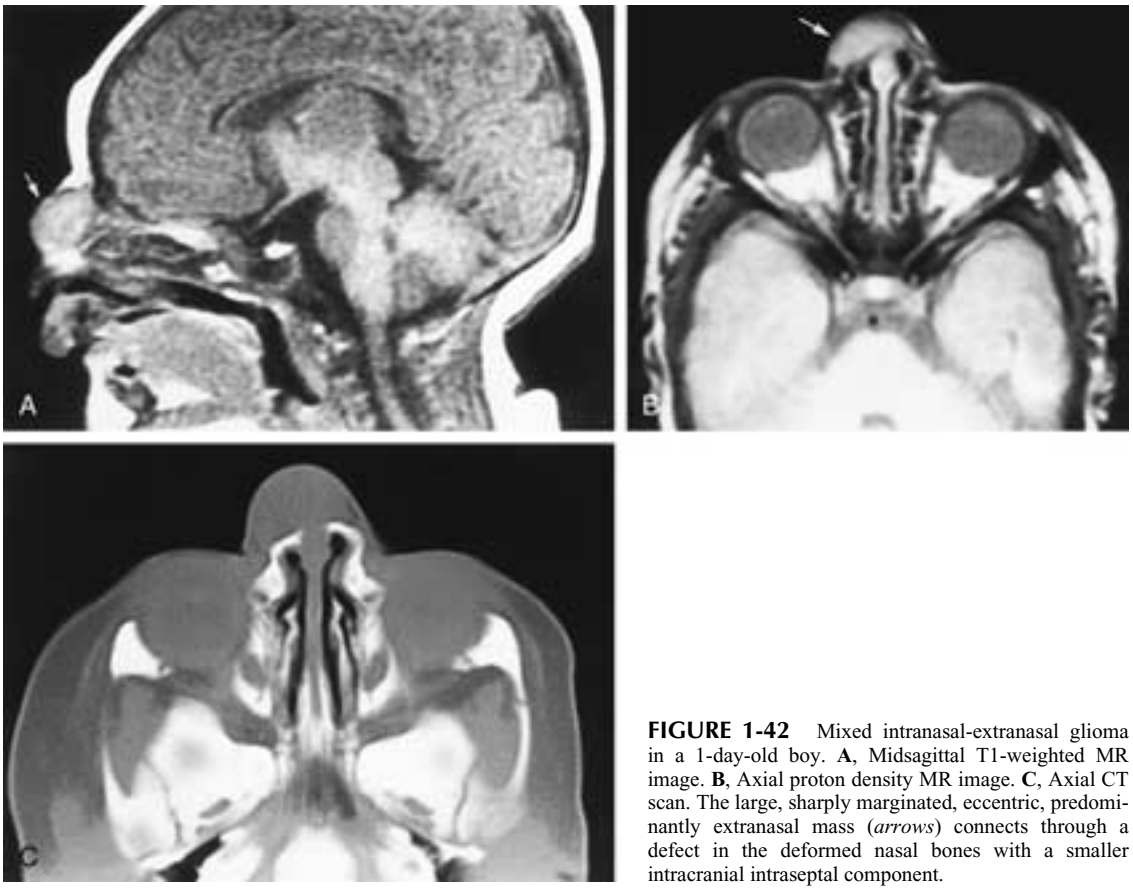

FIGURE 1-42 Mixed intranasal-extranasal glioma in a 1-day-old boy. **A**, Midsagittal T1-weighted MR image. **B**, Axial proton density MR image. **C**, Axial CT scan. SUMMARY BOX 1-1

CLASSIFICATION OF CEPHALOCELES

I. Occipital cephaloceles
   A. Cervico-occipital (continuous with cervical rachischisis)
   B. Low occipital (involving foramen magnum)
   C. High occipital (above intact rim of foramen magnum)
II. Cephaloceles of the cranial vault
   A. Temporal
   B. Posterior fontanelle
   C. Interparietal
   D. Anterior fontanelle
   E. Interfrontal
III. Sincipital cephaloceles
   A. Interfrontal
   B. Frontoethmoidal
      1. Frontonasal
      2. Nasoethmoidal
      3. Nasoorbital
IV. Basal cephaloceles
   A. Transethmoidal
   B. Sphenoethmoidal
   C. Transsphenoidal
   D. Frontosphenoidal
V. Cephaloceles associated with cranioschisis
   A. Cranial-upper facial cleft
   B. Basal-lower facial cleft
   C. Acrania and anencephaly

Modified from Suwanwela C, Suwanwela N. A morphological classification of sincipital encephalomeningoceles. J Neurosurg 1972;36:201–211.

always present as external masses along the nose, orbital margin, or forehead.

Cephaloceles are common lesions, occurring in 1 per 4000 live births.[192, 193] The specific cephaloceles observed vary widely in different populations (Table 1-10). Sincipital cephaloceles are found in 1 in 35,000 live births in North America and Europe but in 1 per 5000 to 6000 live births in Southeast Asia.[194–196] Among Caucasians, occipital cephaloceles are most frequent (67% to 80%), while sincipital cephaloceles (2% to 15%) and basal cephaloceles (10%) are infrequent.[183, 190] Among Australian aborigines, Malaysians, and select Southeast Asian groups, sincipital cephaloceles are the most frequent form encountered. Occipital cephaloceles are closely linked with neural tube defects such as myelomeningocele and show a female preponderance (female : male ratio = 2.4 : 1).[197] Sincipital cephaloceles show no linkage to neural tube defects and no gender predominance.[190, 197]

Interfrontal Cephalocele

The interfrontal cephalocele presents anteriorly as a midline mass situated above the frontonasal suture. In this form, the cranial defect lies between the two frontal bones (Fig. 1-43).

Frontoethmoidal Cephaloceles

Frontoethmoidal cephaloceles are defined as cephaloceles that pass outward from the skull through a defect at the junction of the frontal and ethmoid bones, immediately anterior to the crista galli.[161, 185, 198, 199] Frontoethmoidal cephaloceles are then subclassified into nasofrontal, nasoethmoidal, and nasoorbital subtypes by the point at which the skull defect and hernia emerge *externally* (Fig. 1-44).[185, 196] In 120 Thai patients with frontoethmoidal cephalocele seen from 1992 to 1996, Boonvisut et al.[200] found that the internal ostium was a single opening centered at the foramen cecum anterior to the crista galli in 117 cases (97.5%), and paired, bilateral openings occurred at either side of the crista galli in 3 cases (2.5%). The external ostia of the frontoethmoidal cephaloceles were single or multiple and variable in position.[200] In all cases, the crista galli was intact, and the edge of the defect flared outward like a funnel.

Boonvisut et al.[200] classified the external ostia into type I (a single external opening between two adjacent bones) and type II (multiple external openings clustered in the same region). They then used the term *limited* to mean restricted to the territories within or between two adjacent bones and *extended* to signify extension of the bone defect to adjacent bones beyond the confines of the two bones affected primarily. For simplicity, they considered the narrow frontal processes of the maxilla to be nasal bones when classifying lesion ostia into limited or extended types.[200] In their system, type IA signifies a single ostium situated between or within a single pair of bones (e.g., limited to the frontonasal suture). Type IIA signifies multiple external ostia, each of which is limited to two adjacent bones, and type IIB signifies multiple external ostia, at least one of which is of the extended type. In their 120 cases, 106 (88.3%) of the external ostia were type I (85 type IA and 21 type IB). Fourteen (11.7%) of the external ostia were type II (10 type IIA and 4 type IIB).[200] The individual variations are tabulated in their paper.[200]

The relative frequencies of the individual subtypes of frontoethmoidal cephaloceles may vary with the population. In 120 cases of frontoethmoidal cephalocele from Southeast Asia, 39% were frontonasal, 42% were nasoethmoidal, and 18% were nasoorbital (Table 1-11).[196] In 30 cases from India, however, only 6.7% were frontonasal, 87% were nasoethmoidal, and 6.7% were nasoorbital.[195]

Frontonasal subtype In the frontonasal form of frontoethmoidal cephalocele, the cephalocele emerges from the bony canal between the frontal and nasal bones. The frontal bones are displaced superiorly. The nasal bones, frontal processes of maxillae, and nasal cartilage are all displaced inferiorly, away from the frontal bone, but retain their normal relationship to each other. The ethmoid bone is displaced inferiorly, so that the anterior end of the cribriform plate is depressed, the midline portion of the anterior fossa is very deep, and the crista projects into the defect from its inferior rim. The anterior portions of the medial orbital walls are displaced laterally. In this subtype, the bone canal is short, because the intracranial (frontoethmoidal) and extracranial (frontonasal) ends of the defect lie close together.[185]

Copyright © 2003, Mosby, Inc. All rights reserved.

In patients with the frontonasal subtype, the associated soft-tissue mass usually lies at the glabella or nasal root, between deformed orbits (Fig. 1-45).[184, 185] The mass may be small (1 to 2 cm) or larger than the infant's head. Large masses stretch and thin the skin (partially), obscure vision, and may block the airway.[201, 202] Large masses may also cause pressure deformities of the adjacent soft tissue and bone at the forehead, nose, and orbits and thereby cause telecanthus or true bony hypertelorism. Inferior displacement or lengthening on the medial orbital wall may cause an

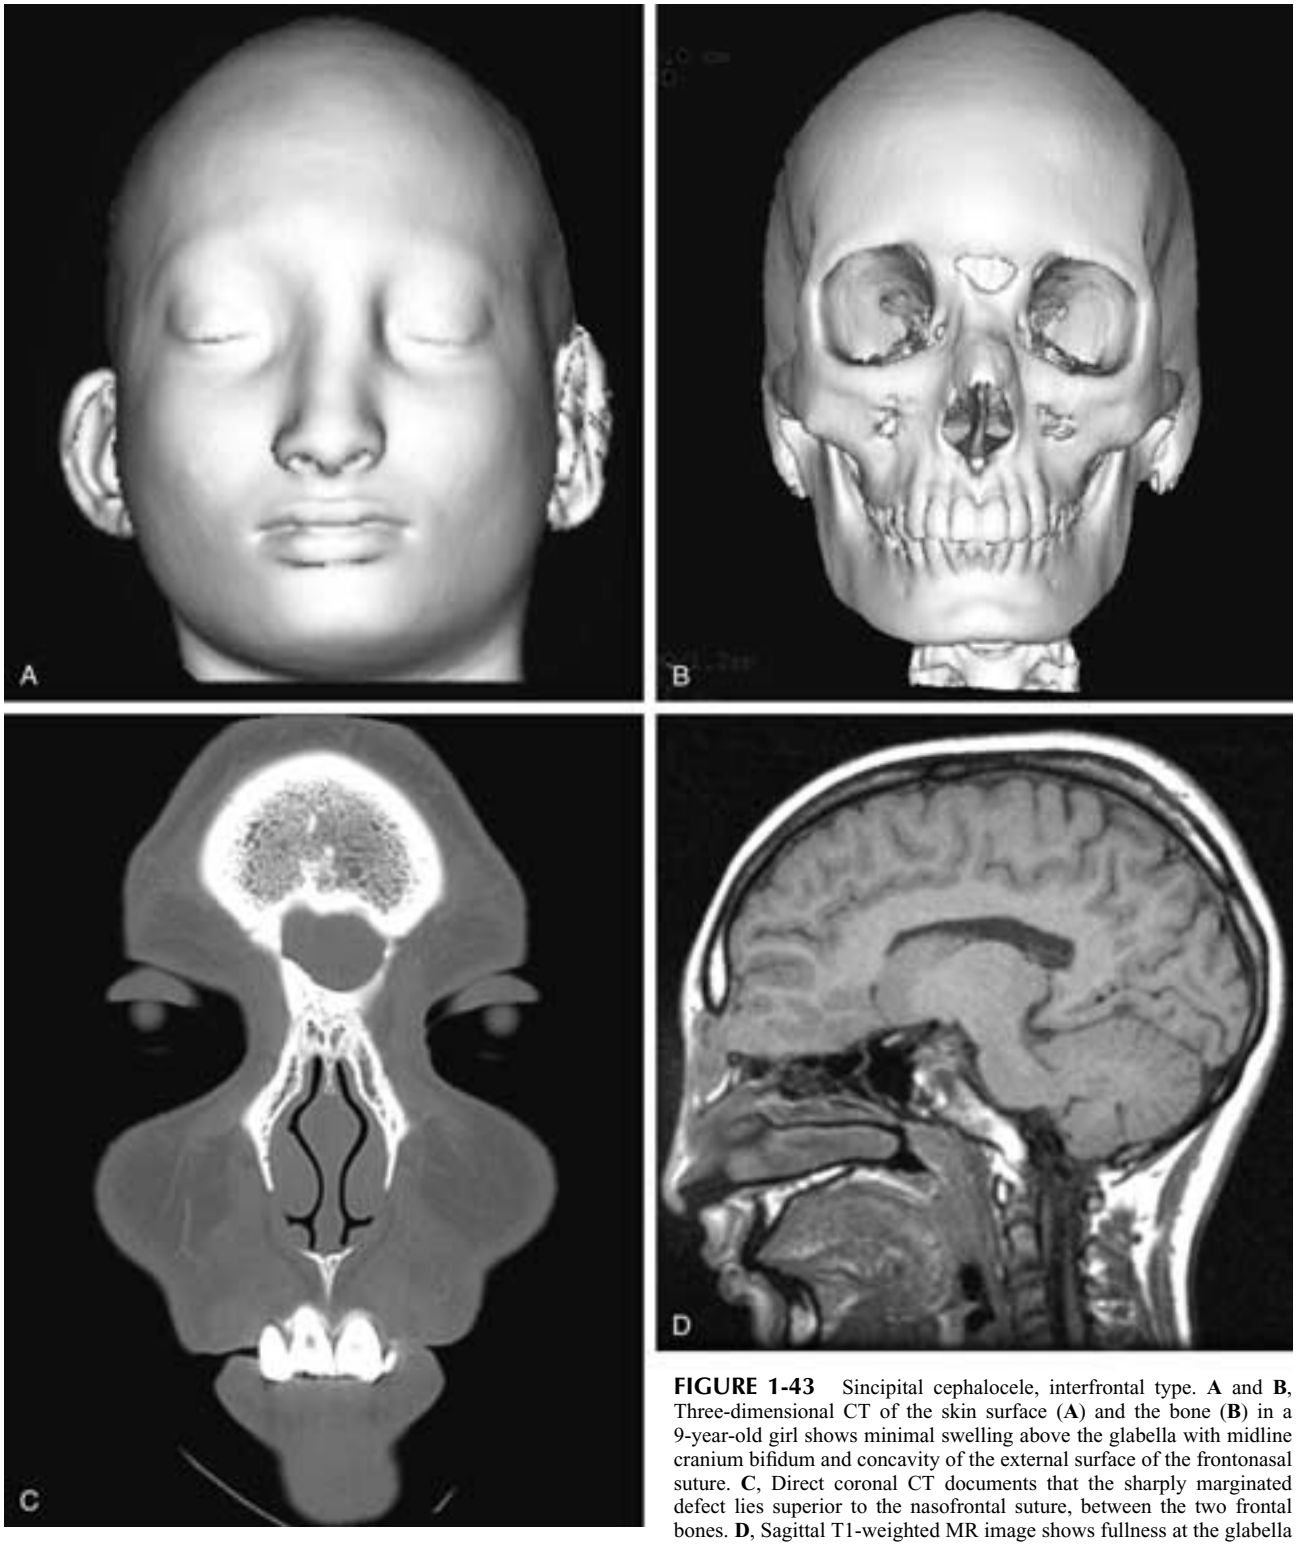

FIGURE 1-43 Sincipital cephalocele, interfrontal type. **A** and **B**, Three-dimensional CT of the skin surface (**A**) and the bone (**B**) in a 9-year-old girl shows minimal swelling above the glabella with midline cranium bifidum and concavity of the external surface of the frontonasal suture. **C**, Direct coronal CT documents that the sharply marginated defect lies superior to the nasofrontal suture, between the two frontal bones. **D**, Sagittal T1-weighted MR image shows fullness at the glabella and herniation of intracranial content through the cranial defect above and external to the nasal bones and nasal capsule.

FIGURE 1-44 **A**, Three-dimensional bone CT of the internal aspect of the skull base shows the internal ostium of a frontoethmoidal cephalocele. All frontoethmoidal cephaloceles exit the skull via a single defect (97.5%) (*arrowheads*) or paired paramedian defects (2.5%) in the anterior fossa just anterior to the crista galli (*arrow*). **B**, Sites of the anterior ostia of frontoethmoidal cephaloceles. Dried adult skull displays the contours and relationships of the individual bones of the skull and face and the intervening sutures. Ethmoid bone or lamina papyracea (*E*), frontal bone (*F*), lacrimal bone (*L*), frontal process of the maxilla (*M*), and nasal bones (*N*). Note the interfrontal, internasal, frontonasal, and frontomaxillary sutures; the nasal spines (*arrow*) of the maxillae; and the lacrimal sac fossa (between the *black arrows*). The anterior crest of the lacrimal sac fossa is formed by the frontal process of the maxilla. The posterior crest is formed by the lacrimal bone. Cartilaginous structures are not displayed. The sites through which the three subtypes of the frontoethmoidal cephaloceles protrude are indicated by the numbered arrows. *1*, Frontonasal cephalocele. The frontonasal forms emerge at the frontonasal junction. The frontal bones form the superior margin of the defect. The nasal bones, frontal processes of the maxillae, and nasal cartilage form the inferior margin of the defect. *2*, Nasoethmoidal cephalocele. The nasoethmoidal forms emerge beneath the nasal bones superior to the cartilaginous nasal capsule. The nasal bones and the frontal processes of the maxillae form the superior margin of the defect. The nasal cartilage and nasal septum form the inferior margin of the defect. *3*, Nasoorbital cephalocele. The nasoorbital forms emerge along the medial wall of the orbit between the frontal processes of the maxilla and the lacrimal-ethmoid bones. The frontal process of the maxilla forms the anterior margin of the defect. The lacrimal bone and lamina papyracea of the ethmoid form the posterior wall of the defect.

FIGURE 1-45 **A** and **B**, Facies. Frontonasal form of a frontoethmoidal cephalocele in 1-week-old girl. The lobulated 3 by 3 by 3 cm skin-covered mass protrudes between the orbits to overlie the nasal bones and nasal cartilage.

antimongoloid slant of the eyes.[202] The size of the soft-tissue mass tends to be proportional to the intracranial pressure, not the size of the internal ostium.[200]

Most frontonasal cephaloceles are firm, solid masses that exhibit no transmitted pulsations. Some are cystic, compressible, and pulsatile and increase in size with the Valsalva maneuver (crying). The mass usually grows as the child grows. Cystic masses may increase in size disproportionately rapidly as CSF pools within the sac. The cephalocele may be covered by intact skin, thin skin that ruptures to leak CSF, or no skin at all, exposing the meninges and brain to the environment. The falx frequently extends into the sac, partially subdividing it. The herniated brain may be well preserved, with recognizable gyri and sulci that converge toward the hernia ostium, or the herniated brain may be reduced to a mass of distorted gliotic tissue. Typically, the brain is not adherent to the base of the sac at the ostium but may be adherent to the meninges at the dome of the sac (60%).[201] The tips of the frontal lobes usually protrude into the defect symmetrically or asymmetrically (Figs. 1-46 and 1-47). The olfactory bulbs may herniate with the brain. The olfactory tracts are stretched. The optic nerves enter the skull normally, but may then recurve sharply anteriorly toward the hernia orifice. The internal carotid arteries course with the optic nerves. The anterior communicating artery may lie near the ostium. Concurrent anomalies such as holoprosencephaly and hydrocephalus may be present.[201]

Nasoethmoidal subtype In the nasoethmoidal form of frontoethmoidal cephalocele, the cephalocele emerges from the bony canal between the nasal bones and the nasal cartilage.The nasal bones and the frontal processes of the maxillae remain attached to the frontal bones above the sac, forming the anterosuperior wall of the canal. The nasal cartilage, nasal septum, and ethmoid bone are displaced posteroinferiorly, forming the posterior-inferior wall of the canal. The crista projects upward into the canal from the depths of the floor. The medial walls of the orbit form the lateral borders of the defect. These can be bony or membranous. In this group, the canal is long, because the intracranial (frontoethmoid) and extracranial (nasoethmoid) ends of the defect lie far apart. In the nasoethmoidal form, the bone defect is usually circular and is situated between the orbits, increasing the interorbital distance. The nasal bones remain attached to the frontal bones along the upper margins of the ostium. The cribriform plate lies at a normal height with respect to the orbits. The soft-tissue mass lies to one side of the midline, beside the nasal cartilage. It may be bilateral.[203] In patients with nasoethmoidal cephaloceles, the soft-tissue mass usually presents below the glabella, along a widened dorsum of the nose.
present on both sides of the nose and may extend to the inner canthus. Hydrocephalus is common. In Suwanwela's series, one of three patients had concurrent agenesis of the corpus callosum with an interhemispheric cyst.[185]

Nasoorbital subtype In the nasoorbital form of frontoethmoidal cephalocele, the cephalocele emerges from the bony canal at the medial wall of the orbit between the maxilla and the lacrimal/ethmoid bones (Figs. 1-48 and 1-49). The abnormal frontal process of the maxilla is displaced anteromedially to form the anterior margin of the defect. The lacrimal bone and lamina papyracea of the ethmoid are displaced posterolaterally to form the posterior edge of the defect.[161] The frontal bones, nasal bones, and nasal cartilage retain their normal relationship to each other. In this subtype, the canal is very long, because the intracranial (frontoethmoidal) and extracranial (medial orbital) ends of the defect are widely separated. Patients with nasoorbital cephaloceles commonly present with cystic soft-tissue masses at the nasolabial folds between the nose and the lower eyelid. These contain nubbins of brain.[185]

Frontoethmoidal cephaloceles induce secondary deformities in the facial skeleton. They impede development of the frontal sinuses, and increase the interorbital and intercanthal distances in most cases. The bitemporal widths and the angles between the lateral orbital walls are usually normal (97.5%), except in cases with microphthalmia or anopia (in which they are slightly decreased).[200] Displacement of the crista galli, the cribriform plate, and the perpendicular plate of the ethmoid bone may lead to maxillary hypoplasia.[204] In all cases, the faces of the patients appear longer than normal and the nasal cartilages are misshapen. The pyriform aperture is shorter and broader than normal and is displaced inferiorly.

Concurrent malformations found in 25 patients with

frontoethmoidal cephaloceles include microcephaly (24%), unilateral or bilateral microphthalmos (16%), hydrocephalus (12%), and seizures (4%).[161] Mental retardation was present in 43% of those old enough to test. CSF leakage and continuous bleeding from the exposed brain were major problems in those cephaloceles that lacked a skin cover or in which the thin skin cover ruptured. Rappoport et al.[201] found significant associated congenital anomalies such as microphthalmos, mental retardation, and syndactyly with appendicular constriction bands in 33% of these patients. In one patient with a large frontoethmoidal cephalocele, an arachnoid cyst overlying the right frontal lobe communicated with the external sac. Mahapatra et al.'s 30 cases of frontoethmoidal cephalocele from India showed hypertelorism (83%), enlarged head (from hydrocephalus) (16%), and microcephaly.[195]

The etiologies of frontoethmoidal cephaloceles have not been established satisfactorily. Clear variations in cephalocle incidence with geographic location and population suggest the possibility of a genetic basis for the lesions. David et al.[204] corrrelated advanced paternal age with frontoethmoidal cephaloceles and suggested an autosomal dominant inheritance pattern. Alternatively, Richards[205] noted an increased incidence of frontoethmoidal cephaloceles in impoverished rice farmers of Cambodia but a reduced incidence of encephaloceles in infants conceived in winter months, leading him to propose that aflatoxins, notably ochratoxin A, may represent a teratogenic cause of frontoethmoidal cephaloceles. Approximately 60% to 85% of frontoethmoidal cephaloceles have a good outcome unless there are concurrent severe anomalies.[191] In Brown and Sheridan-Pereira's series,[206] severe mental, motor, and/or visual handicaps were seen in only 30% and mild motor/visual handicaps in another 10%. The size of the fluid spaces does not determine the patient's prognosis. Imaging of these cephaloceles displays the bony defect, the nature of the herniating tissue, the effect on the adjacent tissue, and any concurrent intracranial ear, nose, and throat malformations.[126, 127, 207, 208]

Basal Cephaloceles

Basal cephaloceles are cephaloceles that protrude through the skull base. They include the sphenoorbital, sphenomaxillary, and sphenopharyngeal cephaloceles.[154, 191]

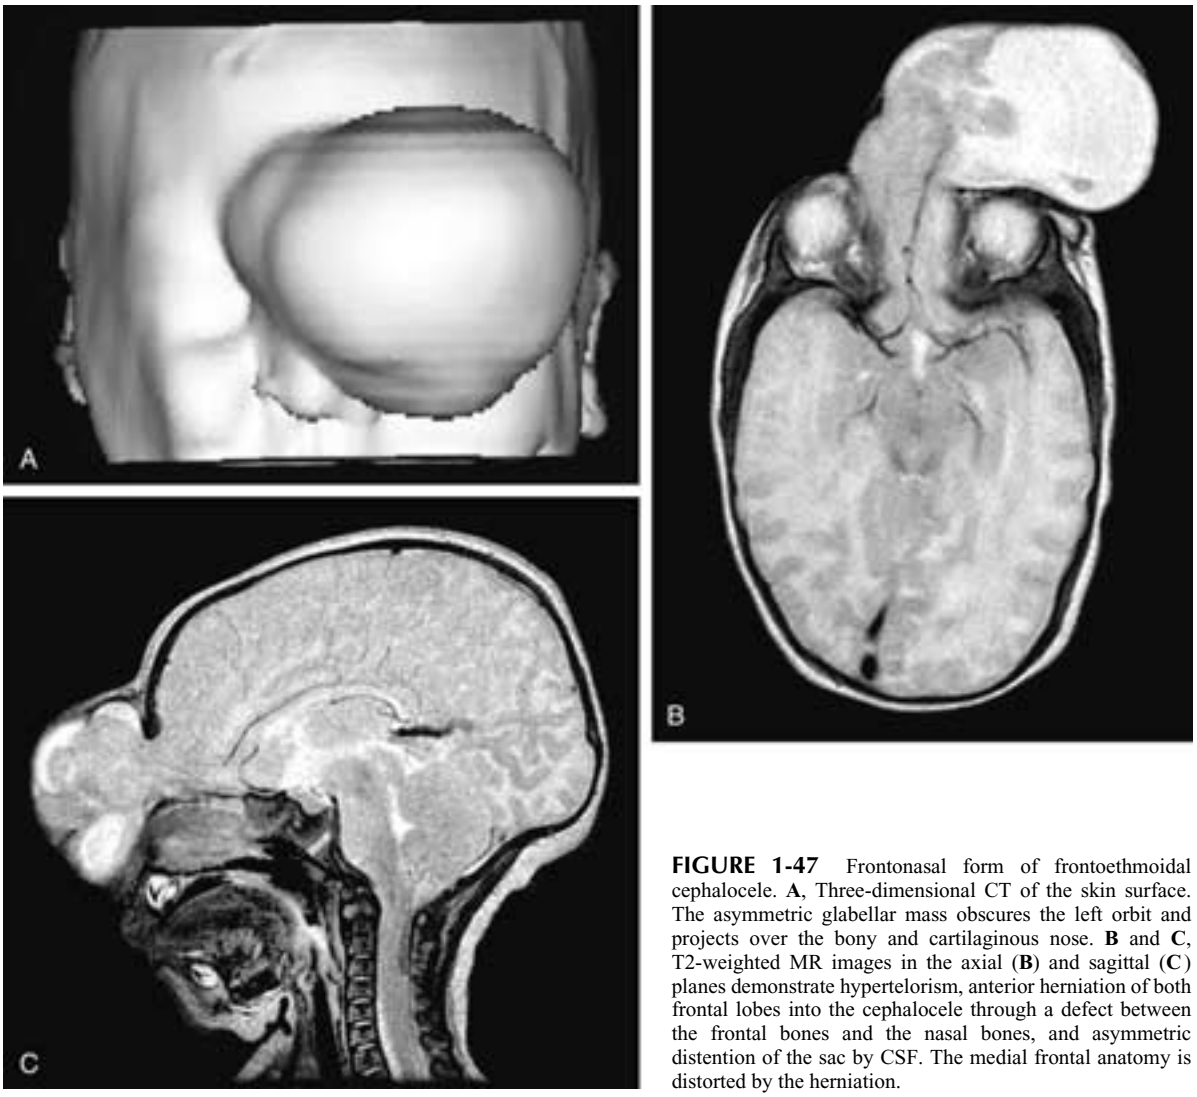

FIGURE 1-47 Frontonasal form of frontoethmoidal cephalocele. **A**, Three-dimensional CT of the skin surface. The asymmetric glabellar mass obscures the left orbit and projects over the bony and cartilaginous nose. **B** and **C**, T2-weighted MR images in the axial (**B**) and sagittal (**C**) planes demonstrate hypertelorism, anterior herniation of both frontal lobes into the cephalocele through a defect between the frontal bones and the nasal bones, and asymmetric distention of the sac by CSF. The medial frontal anatomy is distorted by the herniation.

FIGURE 1-48 *Continued.* **E** and **F**, Sagittal T1-weighted MR images. The paramedian section (**E**) demonstrates the intracranial end (*black arrowhead*) of the osseous canal and direct extension of brain tissue (*white arrow*) into the medial orbit. The lateral section (**F**) demonstrates the prominent arachnoid cyst commonly found in these lesions.

Basal cephaloceles are not visible externally unless they grow large enough to protrude secondarily through the nostril or mouth.[25] They are classified by their point of exit from the skull as sphenoorbital, sphenomaxillary, and sphenopharyngeal.[154] In combined data on 20 basal cephaloceles, 1 (5%) was sphenoorbital, none was sphenomaxillary, and 19 (95%) were sphenopharyngeal.[197, 209]

Sphenoorbital Cephaloceles

Sphenoorbital cephaloceles exit the skull via the superior orbital fissure and come to lie in the orbit posterior to the globe.

Sphenomaxillary Cephaloceles

Sphenomaxillary cephaloceles exit the skull via the superior orbital fissure to enter the orbit, but then pass further inferiorly via the inferior orbital fissure to reach the pterygopalatine space. From there they may extend further into the infratemporal fossa.[210]

Sphenopharyngeal Cephaloceles

Sphenopharyngeal cephaloceles exit from the skull through or between the sphenoid and ethmoid bones. This group is then subclassified (from anterior to posterior) as purely transethmoidal, sphenoethmoidal, or purely transsphenoidal. In the same combined series of 20 cephaloceles, the subtypes of the 19 sphenopharyngeal cephaloceles were transsphenoidal (5 of 19, 26%), sphenoethmoidal (2 of 19, 11%), and transethmoidal (12 of 19, 63%).[158, 197]

Transethmoidal cephaloceles (63%) extend downward anteriorly, through a defect in the midline or along the cribriform plate, and do not involve the sella turcica.[197, 204, 209, 210] The hernia sac extends inferiorly into the sinuses or the nasal cavity[211] and typically contains portions of the frontal lobes and olfactory apparatus. *Transsphenoidal cephaloceles* (26%) extend downward posteriorly, through a defect in the floor of the sella turcica, to reach the nasal cavity (Figs. 1-19 and 1-20).[197, 209] If the palate is cleft, they may also extend further inferiorly into the oral cavity. The posterior margin of these defects is always the dorsum sellae. The lateral walls are the cavernous sinuses and the widely separated halves of the sphenoid bone. The anterior extent is very variable. The defect may involve the sella only or the sella plus the planum sphenoidale. *Sphenoethmoidal cephaloceles* (11%) extend downward through a combined sphenoidal and ethmoidal defect.[197, 204] In our experience, these are nearly always especially large transsphenoidal cephaloceles that extend unusually far anteriorly to involve the ethmoid bone.

As a group, the transethmoidal, transsphenoidal, and sphenoethmoidal cephaloceles are associated with hypertelorism, midline facial clefting, ocular clefting/colobomas, optic nerve dysplasia, and midline cerebral defects. They may be considered together as a craniofacial-cerebral dysraphic complex (Table 1-4). Blustajn et al.[217] noted dysgenesis of the internal carotid artery in two patients with transsphenoidal cephaloceles, hypopituitarism, hypertelorism, and optic nerve coloboma and suggested that all aspects of the syndrome might represent a disorder of neural crest migration. The transethmoidal group tends to have minor facial anomalies (two of three hypertelorism, two of three cleft lip/cleft palate), so they present later in life.[209] The transsphenoidal cephaloceles typically show more severe hypertelorism and facial clefting. The cephalocele sac contains the pituitary gland and the hypothalamus, the anterior recesses of the third ventricle, and the optic apparatus. Symptoms vary. In neonates and infants, the intranasal/pharyngeal soft-tissue mass usually causes a runny nose, nasal obstruction, mouth breathing, or snoring. Frequently, these symptoms are ignored.[218] If they are noted, the intranasal lesions then discovered may be mistaken for nasal polyps, as is true of nasal gliomas.[134] If the early signs are not appreciated, the basal cephaloceles may not be detected until adulthood, when they tend to

VIEW IMAGE

present with visual disturbance, pituitary-hypothalamic dysfunction, or CSF rhinorrhea.[218] Basal cephaloceles, particularly transsphenoidal cephaloceles, carry a high operative mortality rate (50%) and a high risk of chronic severe neuroendocrine handicaps (70%).[191]

Rarer Basal Cephaloceles

Other forms of basal cephalocele are seen very infrequently. Losken et al.[210] identified a group of cephaloceles that entered the orbit directly by downward extension between the ethmoid bone medially and the orbital plate of the frontal bone laterally, *not* via the cribriform plate and *not* via the superior orbital fissure.[210] These authors designated this new group anterior ethmoidal cephaloceles (if the ostium lay close to the anterior ethmiodal foramen) and posterior ethmoidal cephaloceles (if the ostium lay close to the posterior ethmoidal foramen). Elster and Branch[219] and Soyer et al.[220] each reported a transalar form of sphenoidal cephalocele that extended downward through the greater wing of the sphenoid into the pterygoid fossa. Raftopoulos et al.[221] described a variation in which the cephalocele appears to have extended inferiorly through the sphenopetral fissure via the anterior foramen lacerum, displacing the foramen ovale anterolaterally.

DACRYOCYSTOCELES

Dacryocystoceles are the distended nasolacrimal ducts/sacs that result from imperforation of the lacrimal system in the newborn period and shortly thereafter.[222, 223] They are the second most common cause of neonatal nasal obstruction, after choanal atresia, and may require prompt therapy.[208] Dacryocystoceles commonly present as 5 to 12 mm round, tense blue to blue-gray masses situated just inferior to the medial canthi (Fig. 1-50).[222] In the newborn, therefore, dacryocystoceles may be confused with cephaloceles, especially the nasoorbital form of frontoethmoidal cephalocele.

Dacryocystoceles are usually unilateral, in either eye, but may be bilateral in 13% to 65% of cases.[223–226] Males and females are affected equally.[225–228] Nearly all cases are sporadic. The lacrimal *production* system is mature at birth, so full-term infants make tears from the first day of life on.[229] The volume of tears does not correlate with birth weight, placental weight, Apgar score, or maturity of the placenta.[229] However, the distal end of the nasolacrimal duct remains imperforate in many full-term newborns, estimated variably at 6% to 84%.[230–232] The incidence is known to be higher in premature and stillborn infants, perhaps because

Copyright © 2003, Mosby, Inc. All rights reserved.

stretching of the mucosa by breathing and crying helps to open the inferior end of the nasolacrimal duct.[233] Most neonatal dacryostenoses resolve spontaneously. In two series of uncomplicated congenital dacryostenoses, 90% of obstructed tear ducts opened spontaneously at 1 to 13 months of age.[227] Eleven percent required probing to open the duct.[223] Some of those with spontaneous opening of the obstruction re-present in adulthood with renewed stenosis and/or infection.

In 2% of patients with imperforate *distal* nasolacrimal ducts, concurrent obstruction of the *proximal* ducts creates a distended lacrimal sac cyst designated a lacrimal sac mucocele, amniocele, or dacryocystocele.[233, 234] Dacryocystoceles are sterile at birth and asymptomatic. They manifest as excessively large tear menisci along the lower lid margins, crusting of dried mucoid material along the lashes, and epiphora. Secondary dacryocystitis occurs in 0.5% to 6% of these patients and infrequently (2%) leads to a dacryopyocele (lacrimal sac abscess).[225] Periorbital cellulitis and septicemia may ensue.[232]

In approximately 11% to 24% of patients with dacryocystoceles, the distal intranasal end of the nasolacrimal duct distends to form an endonasal cyst (the nasolacrimal mucocele), which may cause partial or complete airway obstruction (Fig. 1-51).[231, 235, 236] These cysts are bilateral in about half of the patients (43% to 48%). Unilateral or partial bilateral obstruction presents as noisy breathing, increased inspiratory effort, restless sleep, and poor sucking. Because 80% of neonates show normal cyclic vasocongestion of the nasal mucosa on alternating sides, patients with unilateral endonasal cysts or partial bilateral obstruction may suffer cycles of respiratory distress when normal nasal engorgement reduces the residual airway. Because neonates breathe predominantly through the nose and will not open their mouths spontaneously to breathe, significant bilateral endonasal obstruction becomes an acute airway emergency, relieved suddenly when crying or mechanical devices open the mouth. Patients with an endonasal component of the dacryocystocele suffer dacryocystitis more frequently.[237, 238]

HOLOPROSENCEPHALY

The term *holoprosencephaly* was coined by DeMyer and Zeman[239] to include a group of cerebral malformations characterized by ''the tendency for the prosencephalon to remain as a whole, as a simple vesicle incompletely transformed into a complex di- and telencephalon with lobes and hemispheres'' (Fig. 1-52). It is characterized by hypoplasia or aplasia of the rostral brain and of the premaxillary segment of the face. Holoprosencephaly is the most common congenital brain malformation in humans.[240] It is found in 1 per 250 concepti but shows very high intrauterine lethality.[240–242] For that reason, the *clinical* incidence of holoprosencephaly is estimated to be 1 in 13,000 to 18,000 live births.[243] There is a female predominance.[244] Surviving patients with severe holoprosencephaly suffer developmental delay, failure to thrive, seizures, poor temperature control, and spastic quadriparesis.[245] Individuals with less severe forms of holoprosencephaly may survive past infancy, with developmental delay. They may even appear to be normal, only to be discovered later to have holoprosencephaly. Those with the least severe forms may show only mental retardation.

Approximately 50% of patients with holoprosencephaly show alteration in the number or structure of their chromosomes,[232] especially chromosomes 13 and 18.

FIGURE 1-50 Dacryocystocele. **A**, Frontal view of a 13-day-old girl with a tense bluish mass inferior to the medial canthus on the left. A far smaller lesion of the same type on the right had just subsided. **B**, Direct coronal CT demonstrates the large, tense left cyst (*arrow*) and a smaller right cyst (*arrow).* (**A** from Naidich TP, Heier LA, Osborn RE, Castillo M, Bozorgmanesh A, Altman N. VIEW IMAGE

FIGURE 1-52 Alobar holoprosencephaly with dorsal cyst in a 1-month-old patient with cebocephaly. Gross pathology in situ. View from above at postmortem examination discloses the lissencephalic shield-shaped holoprosencephalon displaced anteriorly against the frontal bones by the large dorsal cyst. The cyst leads directly into the monoventricle deep to an everted hippocampal ridge (*arrowheads*). The holoprosencephalon shows no division into lobes. The diencephalon (*white arrow*) is similarly undivided. There is no falx cerebri. (From Smith MM, Thompson JE, Naidich TP, Castillo M, Thomas D, Mukherji SK. Facies to remember. Cebocephaly with single midline proboscis. Alobar prosencephaly. Int J Neuroradiol 1996;2:251–263.)

Approximately 70% of patients with trisomy 13 have holoprosencephaly.[243] Only 2.1% of patients with trisomy 18 have holoprosencephaly (but holoprosencephalic patients often show trisomy 18).[246] There is a definite association with the Meckel, Kallman, and hydrolethalis syndromes.[247] Recently, holoprosencephaly has been related to deletions and translocations in at least 12 chromosomal regions[248] (Table 1-12).

SIX3 is a transcription factor related to the *Drosophila* sine oculis/optix family of master regulatory genes that can lead to ectopic eye formation. The gene *Sonic Hedgehog* produces an extremely powerful secreted signaling protein (sonic hedgehog) that organizes adjacent tissues, including the notochord, the floor plate of the neural tube, the zone of polarizing activity of the limb bud, the ectodermal tips of the facial proceses, and the apical ectoderm of the second pharyngeal arch.[3] To act, hedgehog protein normally undergoes autoproteolytic cleavage and interacts with cholesterol to create an active, cholesterol-modified amino-terminal segment that remains associated with the membrane and initiates signal transduction.[2, 3, 10, 249] *TGIF* is transforming growth-interacting factor, a modulator of transforming growth factor-alpha. *ZIC2* is a zinc-finger transcription factor gene. The *PATCHED* gene (ptc) codes for a transmembrane receptor that downregulates expression of certain growth factors. *PATCHED* functions in a regulatory feedback pathway with sonic hedgehog, GLI, and Wnt1 (see also the section on Syndromic Craniosynostosis). The hedgehog proteins upregulate several genes, including *PATCHED*. Patched protein then builds up until it interrupts transmission of the hedgehog signal from the cell membrane to the nucleus. Mutations in the *PATCHED* gene cause Gorlin's basal cell nevus syndrome and some sporadic basal cell carcinomas.[250]

Other groups of genes may also play a role in at least some forms of holoprosencephaly. The genes *Otx1* (chro-

Copyright © 2003, Mosby, Inc. All rights reserved.

mosome 2p13), *Otx2* (chromosome 14q21-q22), *Emx1* (chromosome 2p14-p13), and *Emx2* (chromosome 10q26.1) are intimately involved with patterning large portions of the cerebrum, including the medial cerebral wall.[251–254] Recent work on the role of fibroblast growth factor 8 (fgf8) in modulating the expression of *Otx2* and *Emx2* suggest that this factor could also be related to holoprosencephaly.[255]

In humans, holoprosencephaly may be inherited as an autosomal dominant trait that causes haploinsufficiency for sonic hedgehog. At least 27 different mutations of the *Sonic Hedgehog* gene are known to cause a wide range of holoprosencephalic phenotypes.[240, 248, 256, 257] Translocations that mutate upstream regulators of *Sonic Hedgehog* are associated with mild phenotypes of holoprosencephaly.[258]

Classically, holoprosencephaly has been related to maternal diabetes and in utero exposure to radiation, alcohol, cocaine, *Toxoplasma gondii*, and syphilis.[259] Many teratogens that cause holoprosencephaly are now known to affect *Sonic Hedgehog*. The plant alkaloid jervine, for example, causes holoprosencephaly by inhibiting the tissue response to Sonic Hedgehog.[12] Severe cholesterol deficiency prevents formation of the active signaling moiety of *Sonic Hedgehog* and is the basis for the holoprosencephaly seen in 5% of the RSH/Smith-Lemli-Opitz syndrome.[2] Cleft palate and postaxial polydactyly are also part of this syndrome.[2, 10]

Holoprosencephaly Facies

Patients with severe forms of holoprosencephaly manifest a spectrum of orbital, ocular, nasal, and aural anomalies, including an elongated tube-like nasal analog termed the *proboscis*.[260] As a group, the facies of holoprosencephaly are characterized by hypotelorism (Fig. 1-12A). These facies must be carefully differentiated from the facies of the midline craniofacial-cerebral dysraphisms, in which *hyper*telorism is associated with true midline clefting of the nose and/or lip, cranium bifidum occultum, anophthalmos-microphthalmos, colobomas of the peripapillary retina, basal cephaloceles, dysgenesis of the corpus callosum, and intracranial lipomas. The holoprosencephalic facies are grouped into five major categories (Fig. 1-53).

Cyclopia

Cyclopia (Fig. 1-53A) is characterized by a single median bony orbit, which usually contains a variably well-formed eye. The ''eye'' may consist only of rudiments, may be a single globe with partial formation of one or two cornea(s), or may have partial or complete doubling of the globe(s) within the single orbit. The eyebrows may be absent, present only laterally, or united across the midline (synophrys). The nose may be absent or may consist of an elongated, fleshy, tube-like proboscis that arises from the glabella above the orbit and projects anteriorly. The proboscis has a single external ostium that leads to a blind-ending, mucous membrane–lined canal. No midline septum exists, but other septa, reminiscent of turbinates, may partition the channel. The mouth may be small or absent. The upper lip is present and uncleft, but the philtrum and labial tubercle are usually absent.

Table 1-12
GENES RELATED TO HOLOPROSENCEPHALY

Gene Name	Gene Product	Chromosome Location
HPE1	Product unknown	21q22.3
HPE2	SIX3	2p21
HPE3	Sonic hedgehog	7q36
HPE4	TGIF	18p11.3
HPE5	ZIC2	13q32
PATCHED	Patched protein	9q22.3

Data from Odent S. Attie-Bitach T, Blayau M, et al. Expression of the Sonic Hedgehog (*SHH*) gene during early human development and phenotypic expression of new mutations causing holoprosencephaly. Hum Mol Genet 1999;8:1683–1689.

Ethmocephaly

Ethmocephaly (Fig. 1-53B) is characterized by two separate hypotelorotic orbits, two separate eyes, and a median (or, rarely, a double) proboscis that projects anteriorly from a narrow attachment *between* the two eyes. There is no cleft lip or cleft palate. This facies is transitional between cyclopia and cebocephaly and is exceptionally rare.[261]

Cebocephaly

Cebocephaly (Fig. 1-53C) is characterized by two separate hypotelorotic orbits, two separate eyes, and a single tubular proboscis that attaches along the expected course of the nose and ''reclines on its side'' rather than projecting outward, as in cyclopia or ethmocephaly. The proboscis has a single midline ostium and a single blind-ending, mucous membrane–lined canal. There are no nasal bones or nasal septum; the presence of a nasal septum rules out cebocephaly. No olfactory epithelium or ganglia are present. The upper lip is typically present but may be hypoplastic. The philtrum may be partially formed, but there is usually no well-developed labial tubercle.

Absent Intermaxillary Segment with Central Defect and Hypotelorism

Absence of the intermaxillary segment (Fig. 1-53D) is characterized by two hypotelorotic orbits with two eyes, a flat or absent nasal bridge with hypoplastic alae nasi but no nasal septum, and a pseudomedian cleft of the upper lip (absent intermaxillary segment). The missing intermaxillary segment includes (1) the entire thickness of the middle third of the upper lip (prolabium) that normally forms the philtrum and the labial tubercle, (2) the premaxillary bone with the upper incisors, and (3) the primary palate. The secondary palate may be cleft or not.

Intermaxillary Rudiment with Hypotelorism

This facies (Fig. 1-53E) is characterized by bilateral lateral (common) cleft lip and a hypoplastic intermaxillary segment. The nasal bridge is flat or incompletely elevated but is better developed than in Facies 4 above. The nasal septum is present, but incomplete. The residual intermaxillary segment may be highly rudimentary or moderately well developed. These facies form a continuous spectrum with facies 4 (see above).

Major anomalies of the lower face may also be present in patients with alobar holoprosencephaly, including agnathia, microstomia, anostomia, and otocephaly (ear head).[262]

The complete upper lip, with a hint of a labial tubercle in the midline, could represent either fusion of the nasomedial processes independent of the frontonasal process or fusion of the two maxillary processes across the midline. **B**, Facies 2: ethmocephaly. (Courtesy of Dr. Michael Cohen, Halifax, Nova Scotia, Canada.) **C**, Facies 3: cebocephaly with synophrys (fusion of the two eyebrows across the midline). **D**, Facies 4: absent intermaxillary segment, flat nasal bridge, and rudimentary alae nasi (cf. Fig. 12A). Imaging disclosed alobar holoprosencephaly with dorsal cyst. **E**, Facies 5: hypotelorism with an intermaxillary rudiment (*white arrowhead*). Imaging disclosed lobar holoprosencephaly. (From Smith MM, Thompson JE, Naidich TP, Castillo M, Thomas D, Mukherji SK. Facies to remember. Cebocephaly with single midline proboscis. Alobar prosencephaly. Int J Neuroradiol 1996;2:251–263.)

Brain Malformations

Holoprosencephaly is regarded as a generalized reduction in the forebrain and the frontonasal prominence. As a consequence, the brain is typically microencephalic, weighing only 100 to 150 g at birth (vs. the normal 200 to 300 g).[263] The head is usually microcephalic but may manifest macrocrania when marked expansion of a dorsal cyst distends the intracranial space. Classically, the spectrum of brain anomalies seen with holoprosencephaly is divided into three groups: alobar, semilobar, and lobar forms. In the most severe *alobar form*, the supratentorial brain shows no differentiation into hemispheres or lobes (Fig. 1-52). There is no falx, no interhemispheric fissure, and no superior or inferior sagittal sinus. The deep gray nuclei including the thalami form a single deep gray mass with no (or a rudimentary) third ventricle. The holoprosencephalon contains an undivided monoventricle with no septum pellucidum and no differentiation into lateral ventricles or horns. This monoventricle frequently continues posteriorly into a large dorsal cyst, which displaces the holoprosencephalon anteriorly, close to the frontal bones (Fig. 1-52). The intermediate *semilobar form* is the one most frequently seen in clinical practice. Semilobar holoprosencephaly shows partial development of the interhemispheric fissure, falx, and sagittal sinuses, especially posteriorly. The monoventricle

Copyright © 2003, Mosby, Inc. All rights reserved.

shows partial differentiation into posterior and temporal horns in a ''batwing'' configuration, but no septum pellucidum. A small, partly formed third ventricle partially subdivides the deep gray matter into paired, partially united thalami. A dorsal cyst may be present or absent. The least severe form, *lobar holoprosencephaly*, is characterized by variably complete formation of the interhemispheric fissure, falx, and dural sinuses and at least partial formation of the lobes of the prosencephalon, the horns of the lateral ventricles, and the third ventricle. The development of the brain is most nearly normal posteriorly and substantially less advanced anteriorly. By definition, however, all forms of holoprosencephaly exhibit continuity of the frontal cortex across the midline, where normally the two frontal lobes would be separate.

Correlations Between Facies and Holoprosencephaly

Patients with *alobar* holoprosencephaly show facial abnormalities in 83% to 90% of cases.[239, 264] These abnormalities may be any of the five major categories of facies but often are facies 1 to 3. Therefore, detection of cyclopia, ethmocephaly, or cebocephaly strongly suggests the presence of alobar holoprosencephaly. However, 10% to 17% of patients with alobar holoprosencephaly have milder atypical facial changes or normal facies.[265] Patients with *semilobar* holoprosencephaly show facial anomalies less often, in 30% of cases in some series.[265] These usually are the milder facies 4 and 5 (Fig. 1-54). Facies 3—cebocephaly—can be seen with semilobar holoprosencephaly. Patients with *lobar* holoprosencephaly usually have normal facies but may also show facies 4 or 5 or subtle findings such as a single central incisor.[244]

Osaka and Matsumoto[265] correlated the presence of facial anomalies with the type of holoprosencephaly. In this review, facial anomalies were considered to be clefting of the lip and palate, not milder forms. These authors found an imperfect correlation: facial anomalies were seen in 47 of the 100 cases (47%). In these cases the holoprosencephaly was alobar in 80%, semilobar in 10%, lobar in 0%, ''abortive'' in 0%, and unclassified in 9%. Facial anomalies

FIGURE 1-54 Normal facies with semilobar holoprosencephaly. **A**, Frontal view. This normal-appearing child was evaluated for the small bulge at the upper medial right orbit. **B**, Direct coronal noncontrast CT documents that the orbital lesion (*arrowhead*) is a small dermoid. Absence of the interhemispheric fissure led to MR imaging. **C**, Axial T2-weighted MR image shows semilobar holoprosencephaly with absence of the interhemispheric fissure and falx anteriorly, partial subdivision of a monoventricle into temporal and occipital horns posteriorly (batwing configuration), incomplete third ventricle (*3*), partial separation of the thalami (*arrows*) with union of the deep gray matter (*arrowhead*) anteriorly, and a dorsal cyst (*C*). (From Smith MM, Thompson JE, Naidich TP, Castillo M, Thomas D, Mukherji SK. Facies to remember. Cebocephaly with single midline proboscis. Alobar prosencephaly. Int J Neuroradiol 1996;2:251–263.)

were absent in 53 of the 100 cases (53%). In those patients with no facial anomalies, the holoprosencephaly was alobar in 8%, semilobar in 20%, lobar in 50%, ''abortive'' in 20%, and unclassified in 0%. In at least one study, four patients with concurrent Dandy-Walker cyst and holoprosencephaly had normal facies.[264]

FACIAL AND BRANCHIAL ARCH SYNDROMES

The syndromes of the first and second branchial arches manifest as deficiencies of tissue and as hypoplasias of the maxillary and mandibular arches.

Pathogenesis

Differences among the dysplasias of the first and second branchial arch derivatives may reflect differences in the time of insult with respect to neural crest cell migration and differences in the cells targeted.[266] In mice, neural crest cells destined for the first and second visceral arches begin to migrate out of the neural folds when the embryo has five to nine somites.[266] Exposure to retinoic acid at and just prior to this time causes malformations of the visceral arches that appear to constitute the Goldenhar oculoauriculovertebral (OAV) spectrum (see the section on Hemifacial Microsomia).[266] Exposure to retinoic acid later, after the migration of neural crest cells into the first and second visceral arches is nearly complete, affects the formation of cells from the ectodermal placodes associated with the first and second visceral arches.[266] Excessive cell death initially involving placode-derived cells appears to underlie mandibulofacial dysostosis (MFD) (see the section on Mandibulofacial Dysostosis [Treacher Collins Syndrome]).[266] The normal ganglia are composed entirely of neural crest cells. Placodal cells then migrate into the distal part of the ganglia, where they differentiate rapidly into neuroblasts, while the crest cells contribute to later-differentiating neurons, and supporting Schwann sheath cells and satellite cells.[266] MFD appears to be directly related to excessive and/or premature cell death in the cell populations derived from the first and second ectodermal placodes.[266] Subsequent deficiencies in the tissues that form the dorsal aspects of the maxillary and mandibular prominences of the first visceral arch and the dorsal aspect of the second visceral arch may result directly from localized tissue damage or secondarily from inadequate promotion of growth and/or cytodifferentiation.[266]

Hemifacial Microsomia (Goldenhar Syndrome, OAV Complex)

Concurrent auricular, ocular, and facial anomalies are found in a heterogeneous group of overlapping conditions. Goldenhar described the triad of (1) epibulbar choristomas, (2) preauricular skin appendages and pretragal blind-ending fistulae in association with (3) mandibular facial dysostosis, now called Goldenhar syndrome.[267–269] To these, Gorlin and colleagues added concurrent vertebral anomalies and renamed the complex oculo-auriculovertebral (OAV) *dysplasia*.[270] Rollnick and Kaye then added microtia and called the condition the OAV *complex*.[271] In similar fashion, unilateral hypoplasia of the face and transverse facial clefts, previously termed hemifacial microsomia (HFM), and bilateral, more nearly symmetrical bifacial microsomia (BFM), have also been incorporated into the expanded OAV complex.[272] Further work has linked the OAV complex with the VATER sequence.[272, 273]

HFM is the second most common facial birth defect after cleft lip and palate (Fig. 1-55).[274] Males are affected more frequently than females: (1.2 to 1.8) to 1. The OAV complex

usually arises sporadically but may be familial in up to 21% of cases.[275] About 45% of patients have affected relatives, and 5% to 10% have affected sibs.[271] The specific mode of inheritance and the effect of environmental factors are hotly debated but may be autosomal or X-linked dominant in at least some cases.[276] Among 204 patients with malformations of the external ear (microtia), HFM constitutes 70.5%, isolated microtia 23.5%, Goldenhar syndrome alone 3%, and Goldenhar syndrome within the OAV complex 3% of cases.[275] Goldenhar syndrome accounts for approximately 19% of cases of HFM and 4% to 8% of all cases of OAV complex.[274, 277] The specific incidences of the OAV conditions are estimated at 1 per 3500 to 5600 births for Goldenhar syndrome and 1 per 45,000 live births for the OAV complex.[267]

The OAV spectrum is believed to develop during the first 4 wg, during the period of blastogenesis.[278] Its pathogenesis is unknown. Three theories have been offered[280]: 1. OAV could result from interference with the vascular supply to the region, notably the primordial stapedial artery, leading to local hemorrhage in the developing first and second branchial arches.[276, 279] 2. OAV could reflect impaired interaction between neural crest cells and the branchial arch mesenchyme.[276] 3. OAV could reflect mutations in the *Msx* genes. These genes are a class of homeobox genes expressed in cephalic neural crest cells prior to their migration to form the craniofacial mesenchyme and are critical for differentiation of first branchial arch ectoderm-mesenchyme.[276] Manipulation of the *Msx* genes in mice leads to major abnormalities in first branchial arch derivatives.[281, 282] Similar genes function throughout the body. At present, therefore, the *Msx* genes are candidate genes for the OAV complex and other craniofacial malformations.[276] Some similarity exists between bilateral OAV syndrome and hypoglycemia associated with diabetic embryopathy, but the children with hypoglycemia do not manifest the facial asymmetry typical of HFM-OAV complex.[283]

The stigmata of the OAV complex include anomalies of the face, ears, and eyes, with numerous concurrent malformations of the central nervous system (CNS) (15%), skeleton (41%), heart (26%), gut (12%), and lungs (9%).[284]

Face

Facial asymmetry is seen in about 65% of patients, is severe in 20%,[272] and progresses during childhood.[272] The asymmetry may *not* be appreciable in the infant, but it becomes evident by age 4 years in most cases.[285] The hypoplasia may be predominantly vertical or predominantly transverse, but most patients show mixed vertical-transverse hypoplasia, with the greatest hypoplasia along the oblique line from the (residual) ear to the corner of the mouth (Fig. 1-55). Most HFM is unilateral (up to 94% in some series), but the microsomia may be bilateral in 16% to 35%.[286] The right side of the face is affected far more often than the left. In the *upper face*, the zygoma and the lateral maxilla are most affected.[287–289] The orbits are approximately equal in size in 96%, but differ in their vertical position in two thirds and in their horizontal position in 15% of HFM patients.[290] The interorbital distance remains normal. The nose and columella deviate toward the hypoplastic side. In the *lower face*, the mandible is affected most severely, so *mandibular* hypoplasia accounts for most of the asymmetry seen in HFM (Fig. 1-56). The ramus of the mandible is more severely hypoplastic than the body, so the mandible acquires a steeper slope. These changes cause anteroinferomedial displacement of the temporomandibular joint, lateral rotation of the lower jaw, and posterior displacement of the mandibular angle.[287–289]

The muscles of mastication show reduced volume that is ipsilateral to the side of HFM and roughly proportional to the degree of mandibular hypoplasia. Muscle mass is reduced about 50% in each of the masseter, temporalis, medial pterygoid, and lateral pterygoid muscles in grade 3 mandibular hypoplasia, but muscle mass is symmetrical and nearly normal in patients with only minimal manidibular hypoplasia.[291]

Sessile or pedunculated preauricular skin tags are found between the ear and the corner of the mouth in 20% to 88% of cases.[267] The skin tags are unilateral in 37% and bilateral in 25% of Goldenhar patients (Fig. 1-55). Skin tags may also arise at aberrant sites: retroauricular, nostril, nasal tip, and eyelids. They occasionally are seen in patients with apparently normal ears (4%). Preauricular and facial pits occur in 7% and preauricular sinuses in 6% to 29% of patients, with or without associated skin tags.

Mouth

The mouth may have a short transverse dimension (microstomia) or show marked elongation by unilateral or bilateral transverse facial clefts (Tessier No. 7) (macrostomia) (Figs. 1-15, 1-57). These clefts may appear as open clefts extending well lateral to the vermilion or as thickened fibrous bands on the buccal mucosa, Macrostomia is present in 17% to 62% of HFM patients. Cleft lip and/or cleft palate is common in the Goldenhar group (20%) and those with the full OAV complex (15% cleft palate, 7% cleft lip with or without cleft palate). The upper lip may have a shortened vertical height.[267] The palatal and tongue muscles may be hypoplastic, paralyzed, or both. The palate deviates to the affected side in 39% of HFM patients. Bifid tongue, bifid uvula, and double lingual frenulum have also been reported. About 35% of patients suffer velopharyngeal insufficiency secondary to asymmetric movement of the palate and the lateral pharyngeal wall. The ipsilateral parotid and other salivary glands may be normal, agenetic, or displaced. Ectopic salivary gland tissue may be present as a nasal mass in Goldenhar syndrome. There may be salivary fistulae.[267]

HFM often includes malocclusion and buccal crossbite on the affected side.[292] Dental maturation is asymmetric in half of these patients; however, the side of greater maturation may be either the affected or the unaffected side with equal frequency.[292] The teeth show defects in the primary enamel.[292] The distribution of these defects is concordant with the laterality of the craniofacial anomalies and is most pronounced on the maxillary incisors.[292]

Ears

External Ear

Microtia signifies an ear that is too small and/or malformed (Figs. 1-55 and 1-56).[286] Isolated nonsyndromal microtia is found in 0.016% of all newborns. Approximately 3.1% of microtia patients have Goldenhar syndrome, but microtia is found in up to 68% of Goldenhar patients. The microtia is typically unilateral (66%). Where it is bilateral, it is asymmetric in 65% to 90% of cases. The severity of the malformatiom in the external auditory canal parallels the change in the auricle. The external auditory canal is normal in 98% of those with a normal auricle and abnormal in 58% of grade 1, 100% of grade 2, and 86% of grade 3 microtia.[267]

Middle Ear

The severity of ossicular chain malformation parallels the severity of microtia and of mandibular hypoplasia. The ossicular chain is normal in 96% of those with normal auricles and abnormal in 52% of grade 1, 89% of grade 2, and 95% of grade 3 microtia. Radiologically, middle ear structures are abnormal in 70% of cases. Approximately one third of HFM patients have normal hearing. The rest show sensorineural hearing loss (6% to 16%), mixed conductive-

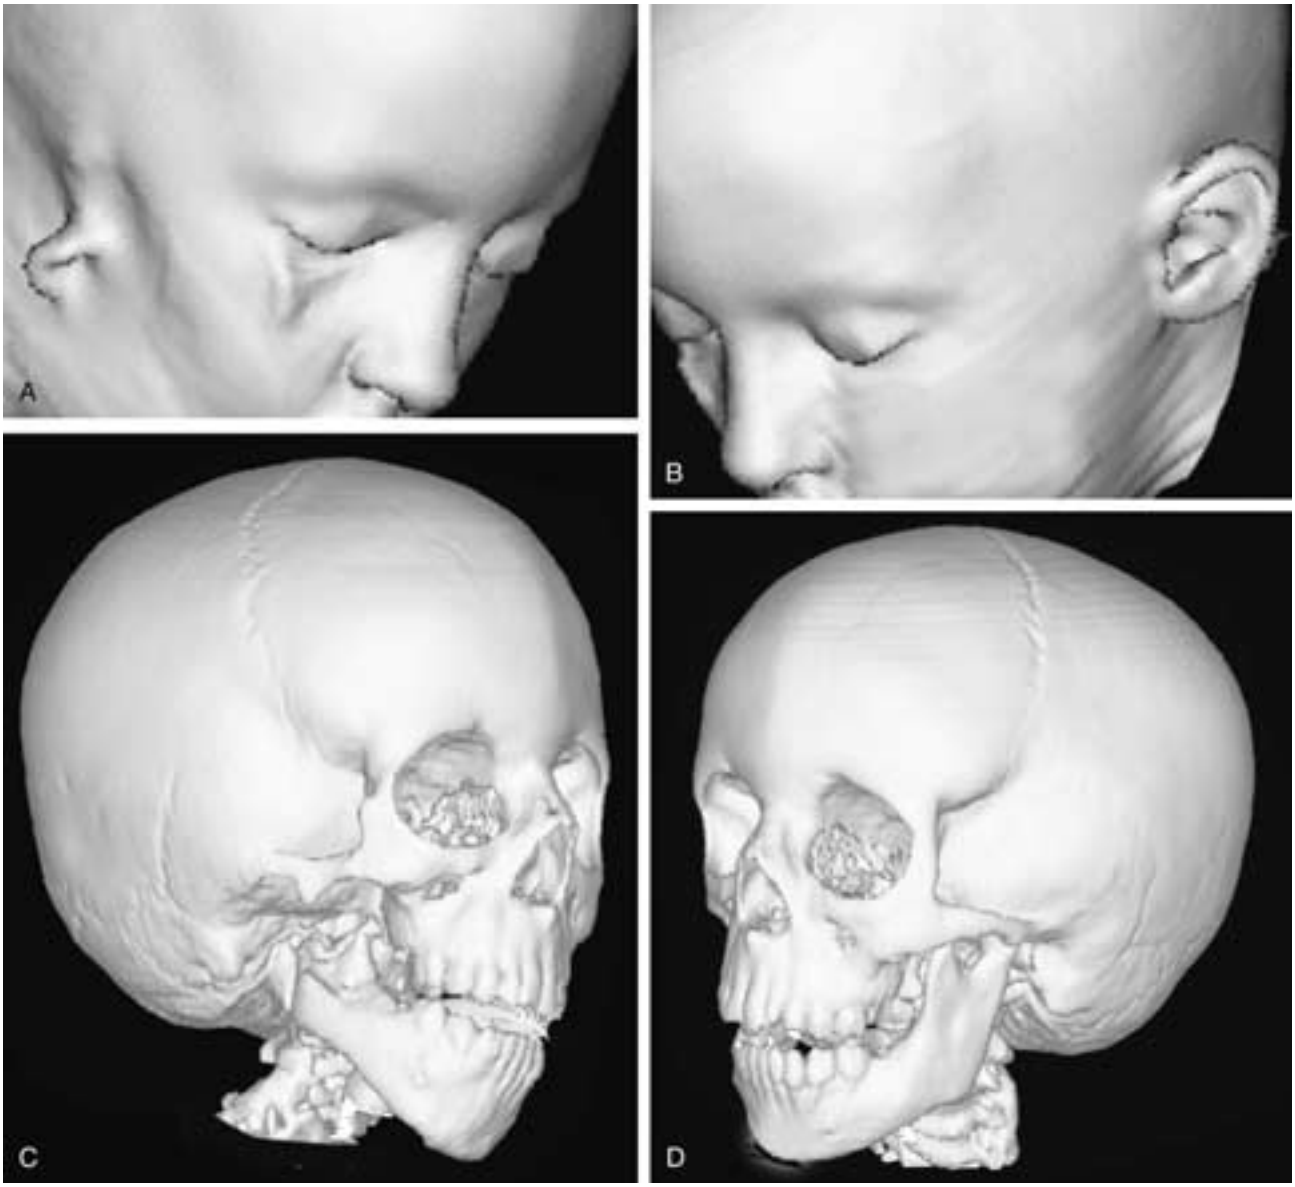

FIGURE 1-56 Goldenhar syndrome with vertebral malsegmentation. **A** to **D**, Three-dimensional CT surface renderings of the skin (**A** and **B**) and bone (**C** and **D**) of the two sides show right hemifacial microsomia with right microtia and hypoplasia of the right zygomatic arch, right maxilla, and right mandible, especially the angle and condylar process of the mandible. The lower right eyelid shows depression of the skin surface that corresponded to a coloboma.

FIGURE 1-56 *Continued.* **E**, Frontal bone surface shows the marked deficiency of the right facial skeleton. **F**, The thoracolumbar spine shows malsegmentation and sharp-angle scoliosis.

sensorineural hearing loss (6%), or purely conductive hearing loss.[293]

Inner Ear

Inner ear anomalies are present in at least 6% of patients with Goldenhar and HFM syndromes (Fig. 1-57).[294, 295] Seventh nerve palsy is seen in 45% of HFM patients and correlates with the severity of the microtia. Radiologically, the facial nerve canal is abnormal in 83% of patients: 7% of grade 1 microtia, 38% of grade 2 microtia, and 63% of grade 3 microtia. The vestibules and semicircular canals may be dilated or small. The common crus may be absent.[296] The internal auditory canal can be asymmetrically smaller, shorter, and inclined upward. The cochlea and vestibule may be abnormal or absent.

Eyes

Characteristic ocular features of Goldenhar syndrome include epibulbar choristomas, colobomas of the upper lid, impaired ocular motility, and dacryostenosis (Fig. 1-58). Epibulbar choristomas are congenital, benign, nonproliferative masses of normal epidermal and connective tissue structures that are situated at abnormal sites. Their etiology is unknown. Choristomas are the most common epibulbar tumor in children.[269, 275, 297, 298] They are found in 4% to 32% of Goldenhar cases, 21% of HFM cases,[290] and 88% of OAV complex cases. Of 50 children with ocular ''dermoids,'' 46% had HFM. Half of these (22%) had signs of Goldenhar syndrome. Among 127 personal and published cases of Goldenhar, Feingold and Baum[269] found that 76% had dermoids (53% unilateral, 23% bilateral) and 47% had lipodermoids (28% unilateral, 19% bilateral). Most choristomas are subconjunctival (59%), often encroaching on the corneo-scleral limbus. A smaller number are limbal (41%). None are corneal.[275] A few arise on the eyelids.

Unilateral or bilateral colobomas of the *upper* lid are seen in 11% to 71% of Goldenhar cases, usually in the medial third or at the junction of the medial and middle thirds (Fig. 1-58).[275] *Lower*-lid colobomas may be seen in 6% of Goldenhar patients' eyes without concurrent upper-lid colobomas, but specific involvement of the lower lid suggests a diagnosis of MFD (Treacher Collins syndrome) rather than the Goldenhar-OAV complex.[293, 299] Other ocular features include ectropion (eversion of the lid margin) (25%), unilateral blepharostenosis (11%), blepharoptosis (2%), anophthalmia/cryptophthalmia/microphthalmia (2% to 12%), impaired ocular motility including esotropia, exotropia, and Duane's retraction syndrome (presumably secondary to hypoplasia of the oculomotor nerve or brain stem nuclei) (10% to 19%), and dacryostenosis (with or without lacrimal fistulae secondary to obstruction at the nasolacrimal duct or lower canaliculus) (11%).[275]

FIGURE 1-58 Hemifacial microsomia. Goldenhar syndrome. This 4-month-old girl shows a large coloboma of the medial portion of the left upper lid (*between the curved white arrows*) and a whitish choristoma (*straight white arrow*) that straddles the corneoscleral limbus inferotemporally. There is a second, small coloboma of the lower lid medial to the choristoma. The caruncle is unusually prominent. (Case courtesy of Dr. Myron Tannenbaum, Miami, Florida.) (From Naidich TP, Smith MS, Castillo M, Thompson JE, Sloan GM, Jayakar P, Mukherji SK. Facies to remember. Number 7. Hemifacial microsomia. Goldenhar syndrome. OAV complex. Int J Neuroradiol 1996;2:437–449.)

Central Nervous System

Total or partial peripheral seventh nerve palsies have been seen in 12% of microtia patients and 22% to 45% of patients with HFM.[290] Seventh nerve palsies correlate well with both the severity of mandibular hypoplasia and the presence of sensorineural hearing loss. Facial paralysis is found in about 50% of grades 1 and 2 mandibular hypoplasia, increasing to almost 70% in grade 3. The trigeminal nuclei and nerve and other cranial nerves may also be deficient. Other CNS malformations, found in 5% to 15% of patients with the OAV complex, include hydrocephalus, absent septum pellucidum, absent corpus callosum, Arnold-Chiari and Dandy Walker malformations, microcephaly with partial anencephaly, anterior cephaloceles, posterior cervicooccipital cerebellocele with vermian agenesis, lipoma of the corpus callosum and vermis, frontal lobe hypoplasia, and unilateral arrhinencephaly ipsilateral to the side of the Goldenhar microtia and HFM.[267]

Plagiocephaly

Approximately 10% of patients with HFM show deformation of the frontal bone on the side of the predominant HFM.[300] The resultant HFM plagiocephaly phenotype mimics coronal synostosis, except that the affected ear is displaced anteroinferiorly, as expected for HFM, rather than posteroinferiorly, as expected for coronal synostosis. These plagiocephalic patients have orbital dystopia (86%), more severe microtia (57%), and a 43% incidence of parenchymal CNS anomalies such as callosal agenesis, encephalocele, and hydrocephalus. Goldenhar syndrome may be found in association with frontonasal dysplasia.[272]

Mandibulofacial Dysostosis (Treacher Collins Syndrome, Franceschetti-Zwalen-Klein Syndrome)

MFD is an autosomal dominant syndrome found in 1 per 50,000 live births. It is now linked to the *TCS* (*TCOF1*) gene at chromosome 5q31.3-q32 and shows variable expression within families.[10, 301] Approximately 60% of cases arise as new mutations. The mutation is thought to interfere with coding for a protein designated *treacle*, leading to haploinsufficiency for this protein.[301] Multiple different mutations within this gene may give rise to the Treacher Collins syndrome.[10] Allelic mutations in the *TCS* gene could explain the partial clinical overlap of the Treacher Collins syndrome with Goldenhar syndrome and Nager acrofacial dysostosis (see the section on Nager Acrofacial Dysostosis Syndrome), but this mechanism has not been proved.[301]

The obligatory features of MFD are marked hypoplasia of the malar bone, with or without malar clefts, hypoplasia of the mandibular ramus and condyle, marked antimongoloid slant of the palpebral fissures, obliteration of the frontonasal angle, colobomas of the lateral third of the *lower* lid with or without those of the upper lid, and/or malformations of the eyelashes (Fig. 1-59).[266, 293, 299, 302] Other stigmata include inferior extension of the hairline onto the cheeks, malformed auricles, deformity or absence of the external auditory canal, malformed middle ear and ossicles with conductive hearing loss, blind fistulae and/or skin tags situated between the auricle and the corner of the mouth, microstomia or macrostomia, abnormal dentition with malocclusion, and antegonial notching of the mandible.[266, 293, 299, 300] Orbital hypoplasia, microphthalmos, lacrimal duct atresia, craniosynostoses, and skeletal malformations have also been reported. Miscarriage or early death is common.[302] One tries to differentiate MFD from the Goldenhar-HFM-OAV complex by observing that MFD mandibles are symmetric bilaterally, with little variation among patients. Patients with MFD show far greater frequency of *lower*-lid colobomas, *marked* antimongoloid slant of the palpebral fissures, and infrequent choristomas, skin tags, and upper-lid colobomas. Facial asymmetry, phenotypic characteristics, and lack of inheritance patterns distinguish bifacial microsomia from MFD.[267]

Branchio-Oto-Renal Syndrome (Ear Pits-Deafness Syndrome)

Branchio-oto-renal syndrome (BORS) is characterized clinically by ear anomalies, hearing loss, preauricular pits, branchial fistulae, lacrimal duct stenoses, and renal dysplasia. There is variable expression within families; first-degree relatives may show varying features of HFM or BORS, but hemifacial microsomia is not a component of BORS itself. The syndrome is inherited as an autosomal dominant trait with high penetrance and variable expressivity. Patients with BORS show multiple different mutations and deletions in the *EYA1* gene at 8q13.3.[10] The gene affected is analogous to the *Drosophila eyes absent* gene.[10]

Nager Acrofacial Dysostosis Syndrome (AFD Nager)

AFD Nager is a form of MFD associated with radial defects. The condition may be sporadic or familial.[303] Craniofacial features include mandibular and malar hypoplasia, dysplastic ears with defects of the external auditory canal, conductive deafness, downward slanting of the palpebral fissures, absent eyelashes in the medial one third of the lower lids, microstomia, cleft palate, and a tongue-shaped extension of hair onto the upper cheek. The radial defects range from thumb hypoplasia to absent radial ray. Some patients with Goldenhar syndrome and radial defects appear to overlap with those with AFD Nager.[303]

Pierre Robin Sequence

The Pierre Robin sequence is characterized by micrognathia, glossoptosis, and cleft palate (Fig. 1-60). Girls are affected more than boys (female : male ratio = 3 : 2).[304] The sequence presents clinically as difficulty breathing, difficulty swallowing, and recurrent attacks of cyanosis.[304] Pierre Robin patients typically have palatal cleft-

ing that may involve both the hard and soft palates or the soft palate only.[304] In 36 Brazilian children with isolated Pierre Robin sequence, all patients showed palatal clefting. The clefts were U-shaped in 27 (75%) (26 complete, 1 incomplete), and V-shaped in 9 (25%). The family history was positive for cleft lip/cleft palate in 27.7% of cases.[304] Thus, ''the primary event occurring in isolated Robin sequence may be cleft palate and not micrognathia. . . .''[304] The Pierre Robin sequence may be observed as an isolated sequence, as one of multiple nonsyndromal defects, or as one component of Stickler syndrome, velo-cardio-facial syndrome (22q11 deficiency), or other named syndromes.[304] Marques et al.[304] suggest that a multifactorial polygenic inheritance best accounts for the features of the Pierre Robin sequence.

PREMATURE CRANIAL SYNOSTOSES

Premature cranial suture synostosis signifies premature closure of one or more of the cranial sutures from any cause.[305, 306] Primary cranial synostoses occur in the absence of underlying brain or metabolic disease. Secondary cranial synostoses occur as the indirect consequence of reduced intracranial volume, often after shunting of hydrocephalus or a cerebral insult. Metabolic cranial synostoses arise from underlying disorders such as vitamin D–related rickets, familial hypophosphatasia, hyperthyroidism, and idiopathic hypercalcemia.[306, 307] Primary synostoses may occur as isolated phenomena (nonsyndromic synostosis, 85%) or as one part of multimalformation syndromes (syndromic synostosis, 15%).[308] Table 1-13 summarizes the distribution of 2137 primary craniosynostoses.[308]

Normally, the sutures become narrower and the fontanelles become smaller as the skull matures (Fig. 1-61). Closure of the suture does not occur along the whole length simultaneously, nor does it necessarily involve the entire depth.[309] The inner endosteal aspect of a suture appears to fuse in a more orderly fashion, whereas the outer ectocranial serrated surface shows greater variation.[309] The fontanelles normally close early: the posterior fontanelle by 8 weeks, the anterolateral fontanelle by 3 months, the anterior fontanelle by 15 to 18 months, and the posterolateral fontanelle by 2 years.[310] The mendosal suture closes first, at several weeks after birth. The metopic suture begins to close during the second year and is completely closed during the third year.[310] The sagittal, coronal, and lambdoid sutures normally close much later, in early to midadulthood.[309] The sagittal suture begins to close at 22 years, the coronal suture at 24 years, and the lambdoid suture at 26 years.[309] These sutures may become fully closed only at 35, 41, and 47 years, respectively.[309] On plain X-rays, the sagittal suture is frequently closed after 35 to 40 years and is usually closed after 50 years.[309] The coronal and lambdoid sutures are frequently closed, at least in part, after 50 years.[309] The sutures bordering the squamous portion of temporal bone never close completely, even in the elderly.[309] However, in analyzing cases of craniosynostosis, it is important to bear in mind that functional closure of the sutures usually occurs at about the time the fontanelles close, well before true bony synostosis develops.

Early descriptions of premature craniosynostosis were based on the physical appearance of the patient.[305, 311–314] Such descriptions of head shape and patient appearance, however, are not specific and do not necessarily predict whether specific sutures will be fused on imaging studies. Terms in common use will now be discussed.

Skull Shape

Scaphocephaly (Dolichocephaly, Canoe Head)

This signifies elongation of the calvarium in the anteroposterior (AP) direction, with narrowing in the transverse dimension (Fig. 1-62A). It usually results from premature closure of the sagittal suture but may reflect, instead, prior deformation of the head due to prematurity, soft bones, poor head control, and prolonged decubitus position of the premature infant's head in the intensive care unit.[311]

Trigonocephaly (Ax Head, Keel-Shaped Deformity)

This signifies sharp, anteriorly directed ridging of the midline frontal contour, usually from metopic synostosis (Fig. 1-62B).[314]

Brachycephaly (Broad Head)

This signifies abnormal widening of the transverse diameter of the calvarium, with a shortened AP dimension.

Copyright © 2003, Mosby, Inc. All rights reserved.

It typically results from coronal or lambdoidal synostoses that limit growth in the AP direction (Fig. 1-62C).

Oxycephaly (Turricephaly, Tower Head)

This signifies superior elongation of the calvarium. It is usually associated with bilateral coronal or bilateral lambdoid synostoses, which redirect brain growth anteriorly toward the anterior fontanelle-metopic suture complex or posteriorly toward the posterior fontanelle and lambdoid sutures.

Plagiocephaly (Skew Head, Asymmetric Head)

This signifies asymmetric contour of the calvarium from (1) positional deformation of the skull, (2) unilateral suture synostosis (usually unilateral coronal synostosis), or (3) asynchronous asymmetric synostoses of multiple sutures

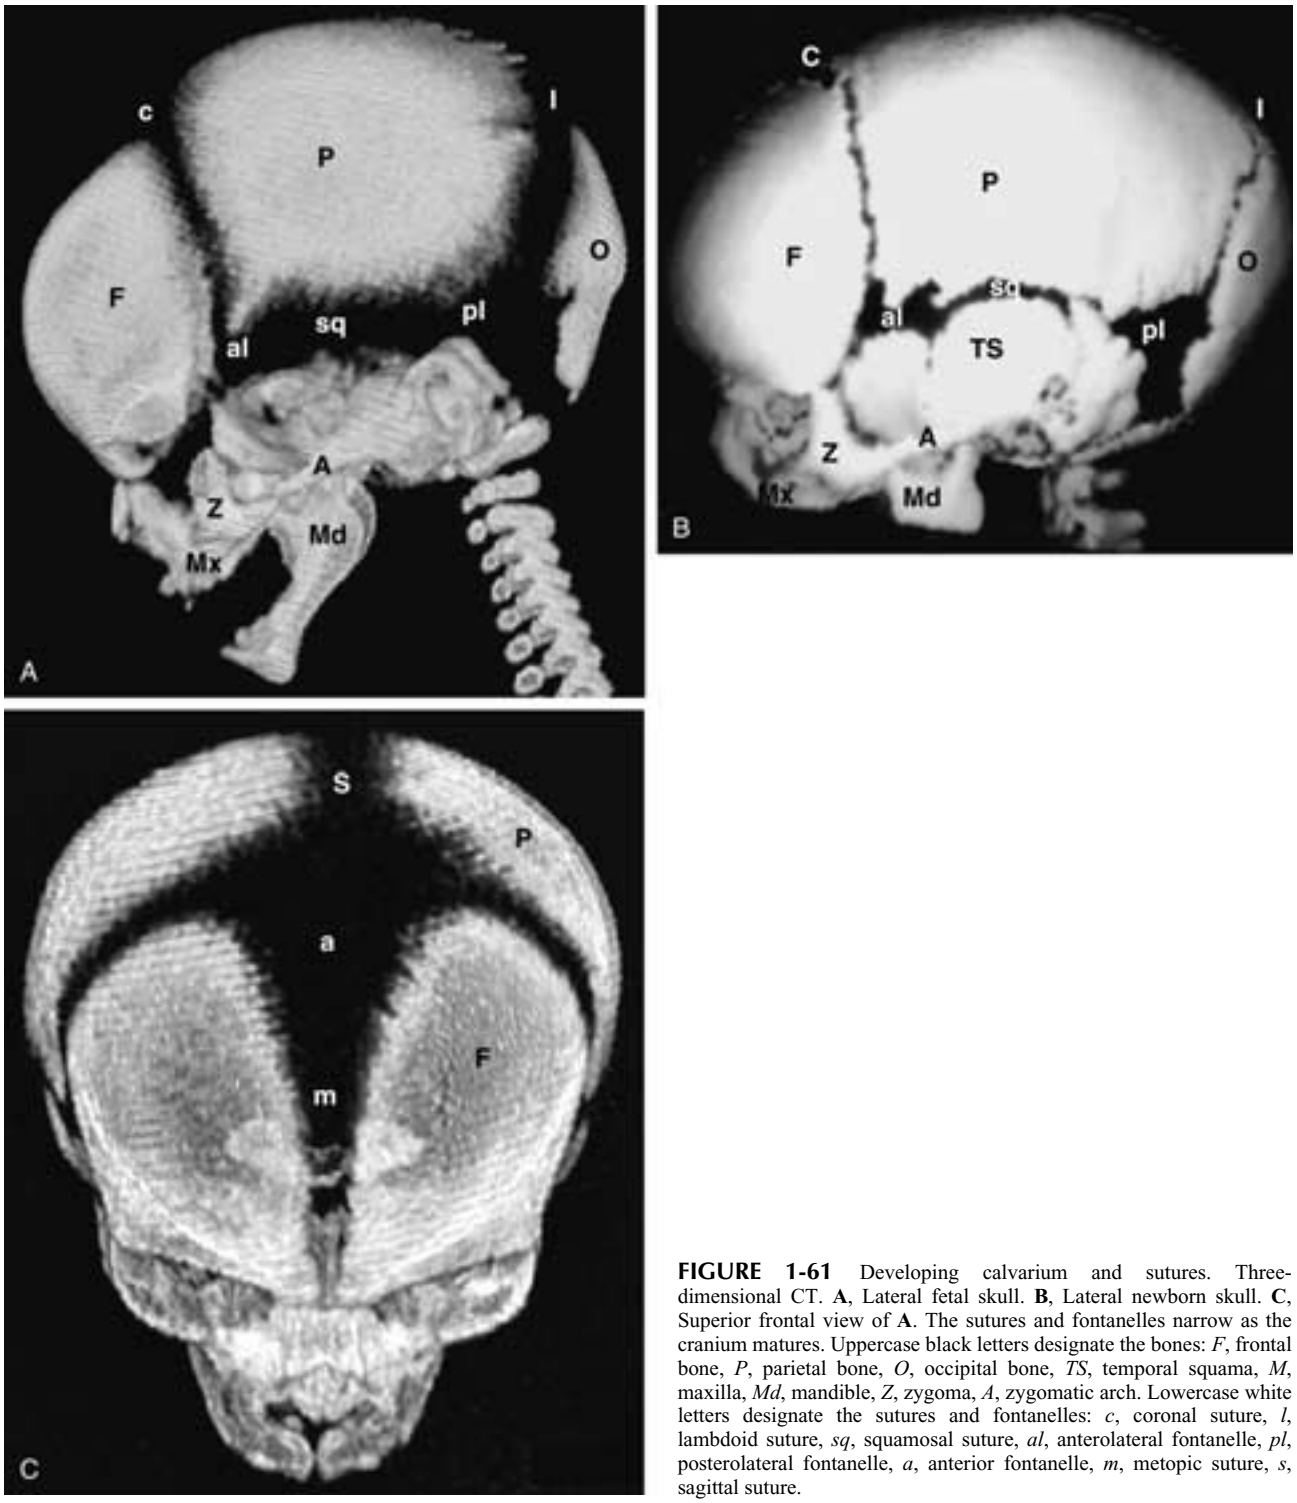

FIGURE 1-61 Developing calvarium and sutures. Three-dimensional CT. **A**, Lateral fetal skull. **B**, Lateral newborn skull. **C**, Superior frontal view of **A**. The sutures and fontanelles narrow as the cranium matures. Uppercase black letters designate the bones: *F*, frontal bone, *P*, parietal bone, *O*, occipital bone, *TS*, temporal squama, *M*, maxilla, *Md*, mandible, *Z*, zygoma, *A*, zygomatic arch. Lowercase white letters designate the sutures and fontanelles: *c*, coronal suture, *l*, lambdoid suture, *sq*, squamosal suture, *al*, anterolateral fontanelle, *pl*, posterolateral fontanelle, *a*, anterior fontanelle, *m*, metopic suture, *s*, sagittal suture.

bilaterally (Fig. 1-62D**)**. At present, the most common cause of cranial asymmetry is a positional deformation of the posterior aspect of the head designated posterior positional plagiocephaly. At present, therefore, the most common referral for possible synostosis is a benign, remediable positional deformation of the skull, not a true premature suture synostosis.[307–313]

Kleeblattschädel (Cloverleaf Skull)

This signifies a trefoil deformity of the calvarium related to severe constriction of calvarial growth at the coronal, lambdoid, and/or squamosal sutures bilaterally. In this condition, remarkable expansion of the temporal fossae inferolateral to the orbits creates the lateral lobes of the cloverleaf, while redirection of growth toward the sagittal suture and fontanelles raises the midline superior lobe (Fig. 1-62E). Exorbitism is often marked. Kleeblattschädel is found most frequently in the syndromal forms of craniosynostosis.

Nonsyndromic Primary Craniosynostoses

Nonsyndromic synostoses constitute 85% of all primary craniosynostoses (Table 1-13). Premature sagittal, coronal, and metopic synostoses are the most frequent forms. Lambdoid synostosis is least common (1% to 3%), affects the midface only incidentally, and will not be discussed specifically.

Premature Sagittal Synostosis

Premature sagittal synostosis is found in 2 to 10 per 10,000 live births and accounts for 40% to 70% of all nonsyndromal craniosynostoses.[306, 313] From 6% to 10% of cases are familial, with autosomal dominant inheritance and 38% penetrance. There is a male predominance (70% to 85% of cases).[313] The abnormal suture is often closed at birth. This restricts transverse growth of the skull, so the patients show scaphocephaly. A palpable ridge or indentation may mark the site of closure. Compensatory growth at the adjacent coronal and lambdoid sutures may lead to frontal bossing, occipital bossing, or both.[313] The anterior fontanelle is often closed. The sphenoid wings and orbits are not affected. As a result, these patients show very prominent foreheads that project far anterior to the orbits but remarkably little facial asymmetry. In contrast to other synostoses, concurrent intracranial abnormalities are exceptionally rare.

Premature Unilateral Coronal Synostosis

Premature unilateral coronal synostosis occurs in 0.7 to 4.8 per 10,000 births and accounts for 14% to 55% of synostoses.[313] Most cases are sporadic. Only 6.6% to 14.4% of cases are familial, with 60% penetrance. There is a slight female predominance (57% to 68%). The curvature of the coronal suture normally extends into the skull base along the adjoining sphenozygomatic, sphenofrontal, and sphenoethmoidal sutures. Unilateral coronal synostosis typically causes growth restriction along much of this arc unilaterally, leading to flattening of the forehead, zygoma, and orbit on the affected side (Figs. 1-62D and 1-63).[313] The eye and eyebrow appear to be displaced up and back (harlequin eye). Compensatory contralateral frontal bossing displaces the contralateral eye inferolaterally. These patients commonly show mild exorbitism, vertical strabismus, horizontal strabismus, and amblyopia.[313] Bone thickening at and surrounding the closed suture may cause a palpable coronal ridge and temporal prominence, but such thickening is far less apparent than is the midsagittal ridging associated with scaphocephaly. The ipsilateral anterior fossa is small. The ipsilateral temporal fossa is rotated toward the midline. The root of the nose is drawn ipsilaterally unless concurrent involvement of the frontosphenoid suture deviates the nose to the opposite side. The ipsilateral maxilla may show vertical hypoplasia. The ipsilateral ear (tragus) is pulled antroinferiorly. The anterior fontanelle deviates to the opposite side. Torticollis is found in about one quarter of these cases.[313]

Premature Metopic Synostosis

Premature metopic synostosis occurs in 1 to 10 per 70,000 births and accounts for 5% to 20% of all cranial synostoses. It is characteristically sporadic, with only 2% to 6% of cases showing familial inheritance, either as an autosomal recessive trait or as an autosomal dominant trait, with very low penetrance.[313] Closure of the metopic suture restricts expansion of the frontal midline, so these patients manifest symmetric lateral sloping of the forehead, short anterior fossa, forward bowing of the coronal sutures, orbital hypotelorism, and ethmoid hypoplasia (Figs. 1-62B and 1-64). The crista galli remains intact. The nasal septum and facial midline are usually straight. The medial walls of the orbits are thickened and rise unusually high. Therefore, the superomedial corners form the highest points of the orbital roofs, and the lateral orbits fall away inferiorly. The degree of orbital deformity correlates with the wedging of the forehead. The frontal lobes, frontal sulci, and ventricles are usually compressed. There may be callosal dysgenesis, hydrocephalus, or other intracranial anomalies.

Syndromic Craniosynostosis (Craniofacial Dysostosis)

The term *craniofacial dysostosis*[2, 10, 307, 315–344] identifies a group of syndromes that exhibit premature synostoses of cranial sutures as one prominent feature. More than 100 such syndromes are recognized.[3] Together they account for 15% of all primary craniosynostoses.[308] Traditionally, craniofacial dysostoses have been classified by their characteristic phenotypes and named by author or place as Crouzon, Apert, Saethre-Chotzen, Pfeiffer, Jackson-Weiss, Boston, and Muenke (Adelaide) syndromes (Fig. 1-65).[321] Recent work shows that such phenotypic classification is imprecise. Mutations of different genes involved in the same pathway create similar phenotypes. Identical mutations in fibroblast growth factor receptor 2 (FGFR2) have been found in patients classified phenotypically as having Pfeiffer and Crouzon syndromes, and in patients classified phenotypically as having Jackson-Weiss and Crouzon syndromes.[10] Therefore, the eponymous craniosynostotic syndromes should now be regarded as phenotypic extremes of FGFR and other mutations, not as nosologic entities. With the

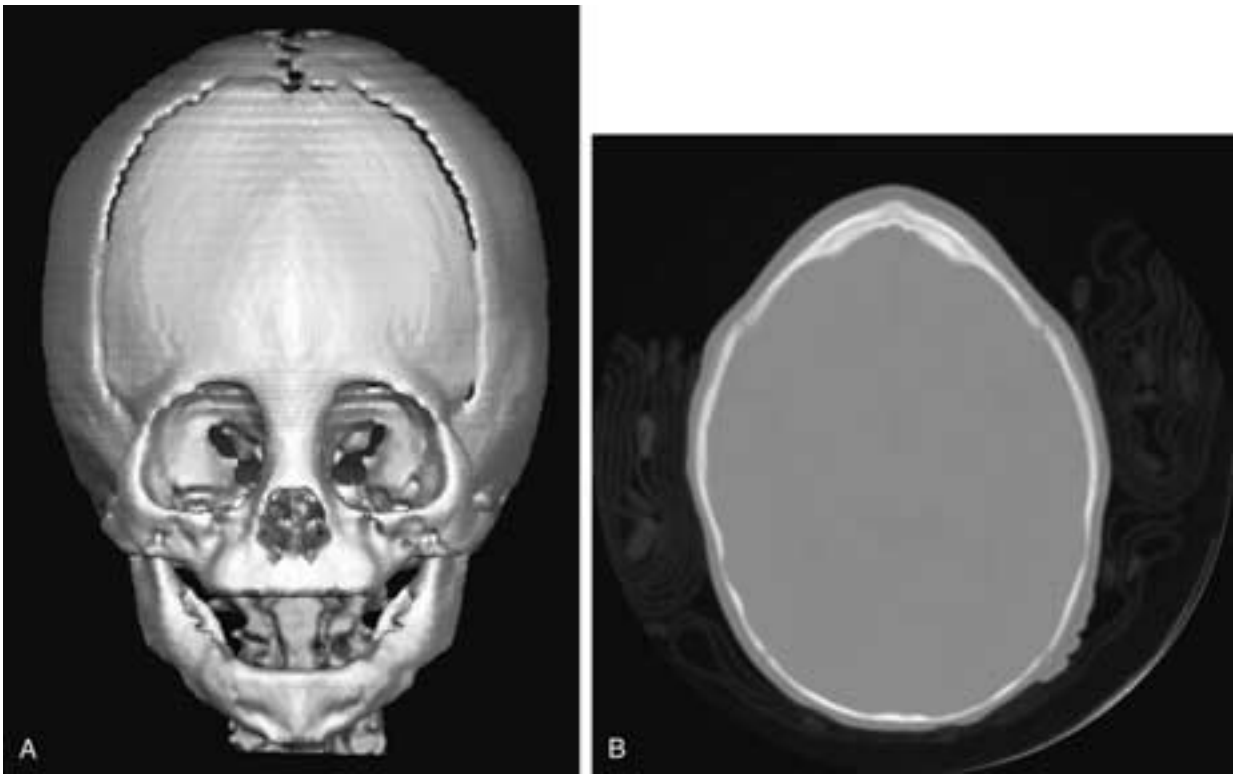
FIGURE 1-63 Nonsyndromal unilateral right coronal synostosis in a 7-month-old girl. **A** and **B**, Three-dimensional CT of the cranial surface (**A**) and a view of the skull base from within (**B**). The right coronal suture and anterior fontanelle are closed. The sagittal and left coronal sutures are patent. The metopic suture is faintly visualized. Asymmetric closure of the right coronal suture restricts growth of the ipsilateral anterior fossa and orbit, causing plagiocephaly, harlequin right eye, short right anterior fossa, high position of the right sphenoid wing-pterion, compensatory bossing of the left frontal contour, and inferior displacement of the left orbit.



VIEW IMAGE

FIGURE 1-64 Trigonocephaly in a 3-month-old girl. **A**, Three-dimensional CT of the facial skeleton. **B**, Axial bone CT through the metopic suture. exception of Apert syndrome (which does show consistent genetics), the clinical phenotypic classifications should be abandoned and replaced with molecular classifications of these syndromes.[326]

Molecular Genetics

Understanding the craniofacial dysostoses requires a background in the cell signaling mechanisms that control suture maturation. The next sections review these mechanisms preparatory to adressing the eponymous craniosynostosis syndromes.

Fibroblast Growth Factor Receptors

Four unlinked genes, *FGFR1* to *FGFR4*, constitute a family of genes that produce high-affinity receptors for the fibroblast growth factors (FGFs 1 to 9).[2] Of these, FGFR1, FGFR2, and FGFR3 are related to suture closure. The chromosomal locations of the FGF genes are: FGF1, 5q31-q33; FGF2, 4q26-q27; and FGF3, 11q13. FGFR genes 1 to 3 are located as follows: FGFR1, 8p11.2-11.1; FGFR2, 10q26; FGFR3, 4p16[326] (Table 1-14).

The FGFR genes encode a group of structurally related tyrosine kinase receptors of the subclass IV type. These FGFRs are situated at the cell membrane and share a three-part structure (Fig. 1-66; see also Fig. 1-1): (1) an *extracellular domain* composed of a variable number of immunoglobulin-like domains (Ig loops), (2) a *transmembrane domain* that bridges the cell wall, and (3) an *intracellular cytoplasmic domain* containing both a tyrosine kinase region responsible for tyrosine kinase activity and an

interkinase region.[10] The immunoglobulin-like domains Ig II and Ig III are necessary for ligand binding.[326] The FGFRs are normally activated (and controlled) by the presence of ligands, which serve as ''on'' signals to initiate phosphorylation. The binding of a ligand to the receptor in the *extracellular* domain normally promotes receptor dimerization. This initiates a sequence of cross-phosphorylation of the *cytoplasmic* domains, provision of binding sites for downstream signaling molecules, conformational changes, and increased kinase activity.[2]

In the craniofacial dysostoses, mutations in the FGFR genes create mutant proteins that allow the receptors to function independently of their normal ligand signals. The mutant receptor proteins form constitutive dimers, which activate the kinase domain and downstream signaling events, even in the absence of ligand.[2] That is, the mutated genes are always ''on,'' a ''gain-of-function'' mutation. Since FGFRs and FGF signaling guide development of multiple different organ systems, including the cranio-facial-oral-dental complex, the group of FGFR malformations exhibits a coherent set of multisystem anomalies affecting the skeleton, the central nervous system, the skin, and the auditory system.[2] The mutations that cause the craniofacial dysostoses cluster in the third Ig loop and in the linker region between Ig loops II and III. FGFRs 1, 2, and 3 each contain an analogous proline in the linker region between Ig loops II and III. Replacement of this proline with an arginine in any of these receptors causes craniosynostosis, with or without other skeletal malformations.[2] In FGFR1, this substitution causes the Pfeiffer syndrome. In *FGFR2*, the equivalent substitution causes Apert syndrome, and in *FGFR3* it causes Muenke nonsyndromic coronal craniosynostosis.[2] By receptor:

FGFR1 In FGFR1, replacement of the proline with an arginine at codon 252 (Pro252Arg) causes Pfeiffer syndrome.[2] Other proline substitutions at position 252 (Pro252) are seen with other nonspecific craniosynostoses.[10]

FGFR2 The FGFR2 gene is involved in most craniofacial dysostoses. Nearly all cases of Apert syndrome show one of two specific missense mutations at codons 252 and 253, which encode the linker region between the Ig II and Ig III domains of the extracellular domain.[10] These Apert-specific mutations consist of substitutions of tryptophan for serine at nucleotide 252 (Ser252Trp) or of arginine for proline at nucleotide 253 (Pro253Arg).[10] The Ser252Trp mutation accounts for 65% of Apert cases and, more commonly, causes concurrent cleft palate. The Pro253Arg mutation accounts for 35% of Apert cases and has a greater association with syndactyly.[327] A mild form of Apert syndrome has also been related to a different FGFR2 mutation, predicted to substitute phenylalanine for serine at position 252 (Ser252Phen-predicted). A study of 57 Apert

patients has shown an exclusively paternal origin of the mutation, which is thought to be related to advanced paternal age.[328]

Other FGFR2 mutations also cause craniofacial dysostoses. Substitution of leucine for serine at position 252 (Ser252Leu) or of serine for proline at position 253 (Pro253Ser) causes Crouzon-like and Pfeiffer-like phenotypes with only mild craniosynostosis.[10, 326] Mutation in the Ig IIIc portion of the extracellular domain of FGFR2 may produce the Jackson-Weiss syndrome.[329]

FGFR3 FGFR3 is the site of a spectrum of mutations that cause disorders of the axial and appendicular skeleton. These include achondroplasia, hypochondroplasia, and thanatophoric dysplasia II, as well as skin disorders. Achondroplasia is associated with a point mutation in the transmembrane domain of FGFR3 (Fig. 1-65B). A study of 10 achondroplasia patients showed an exclusively paternal origin of the mutation, which is thought to be related to advanced paternal age.[317] Hypochondroplasia is associated with a mutation in the intracellular tyrosine kinase domain of FGFR3. The form of thanatophoric dysplasia with cloverleaf skull is associated with mutation of the *extra*cellular domain of FGFR3, whereas the form of thanatophoric dysplasia without cloverleaf skull is associated with a mutation of the *intra*cellular domain of FGFR3.[10] Crouzon patients with concurrent acanthosis nigricans and Chiari I malformation show a specific mutation in the transmembrane domain of FGFR3 (Ala391Glu) at 4p16.3, just 11 amino acids away from the mutation site of achondroplasia.[10] In FGFR3, substitution of arginine for proline at codon 250 (Pro250Arg) is associated with Pfeiffer syndrome. Other proline substitutions at this site have been observed with nonspecific craniosynostoses.

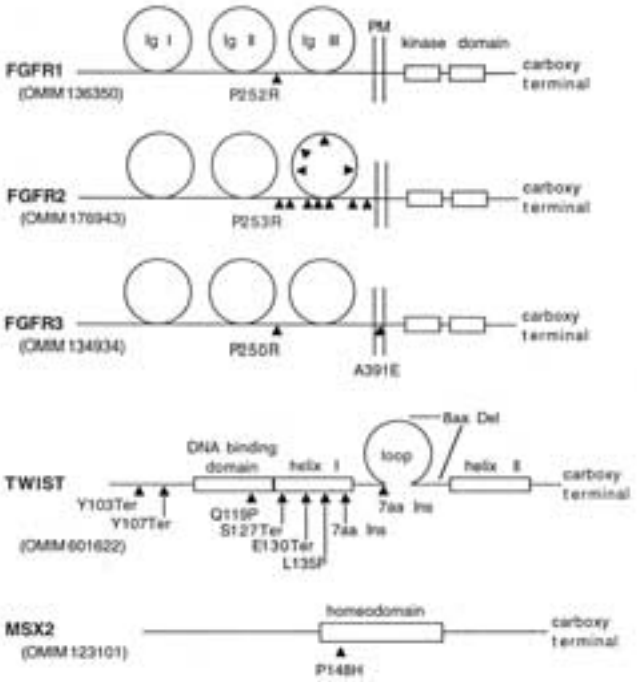

FIGURE 1-66 Molecular genetics of craniosynostoses. The craniofacial dysostoses reflect underlying derangements in signal transduction (see also Fig. 1-1). Diagrammatic representations of FGFRs 1 to 3, the basic helix-loop-helix transcription factor TWIST, and the homeodomain transcription factor *MSX2*. Each molecule is oriented horizontally, with the amino terminal to the left and the carboxy terminal to the right. FGFR 1 to 3. These receptor tyrosine kinases show a similar structure with (1) an extracellular domain composed of three Ig-like loops (Ig I to Ig III) and interposed linker regions between the loops, (2) a transmembrane domain that spans the plasma membrane (PM), and (3) an intracellular kinase domain. By convention, amino acid substitutions are designated by citing from left to right: the normal amino acid, the position at which that amino acid normally resides (counting from the amino terminal of the protein), and last, the new amino acid that has replaced the normal original. Each FGFR has a highly conserved proline at a slightly different position within the linker region between Ig II and Ig III. Amino acid substitutions at that site lead to craniofacial dysostoses. Illustrated here are substitutions of arginine (R) for proline (P) in FGFR1 (P252R), in FGFR2 (P253R), and in FGFR3 (P250R). Numerous other mutations in FGFR2 (*arrowheads*) also produce craniosynostoses. **TWIST**. Multiple mutations along the *TWIST* gene cause Saethre-Chotzen syndrome. ***MSX2***. A single point mutation in the homeodomain of *MSX2* can cause Boston-type craniosynostosis. *S*, serine; *P*, proline; *R*, arginine; *Y*, tyrosine; *L*, leucine; *Q*, glutamine; *H*, histidine; *A*, alanine; *E*, glutamic acid; *aa*, amino acid; *T*, termination, stop codon; *Del*, deletion; *Ins*, insertion. Additional mutations are discussed in the text. (From Nuckolls GH, Shum L, Slavkin HC. Progress toward understanding craniofacial malformations. Cleft Palate-Craniofac J 1999;36:12–26.)

Other Signaling Systems

Derangements of other genes and transcription factors may also be responsible for craniosynostoses.

GLI3 GLI3 is one of three members of a vertebrate family of zinc finger transcription factor proteins designated GLI (because they may be found in gliomas).[2] GLI interacts with hedgehog to affect expression of hedgehog responsive genes. In the absence of hedgehog, GLI is cleaved to a short form that represses hedgehog target genes. The presence of hedgehog preserves the full-length, active form of GLI and thereby allows hedgehog-responsive genes to be expressed.[18, 325] Known homology to the cubitus interruptus (*Ci*) gene in *Drosophila* predicts several functional domains for *GLI3*, including a DNA-binding zinc finger domain and a microtubule-binding domain.[2] Mutations in *GLI3* causes three distinct clinical disorders, two of which result in craniofacial dysmorphogenesis:

1. *Greig cephalopolysyndactyly* (GCPS) is an autosomal disorder defined predominantly by postaxial polydactyly of the hands and preaxial polydactyly of the feet with syndactyly. The craniofacial features of this disorder include macrocephaly with broad forehead, hypertelorism, broad nasal root, and occasional craniosynostosis. Mutations in *GLI3* associated with GCPS cause truncation of the molecule within the centrally located zinc finger domain and probably result in functional haploinsufficiency.[2]
2. *Pallister-Hall syndrome* (PHS) is caused by a frameshift in the *GLI3* sequence just downstream of the zinc finger domains, resulting in a differently truncated protein, which potentially retains partial function and DNA binding. PHS patients exhibit hypothalamic hamartomas, craniofacial anomalies, and polydactyly of the hands, usually central or preaxial. They do not display the hypertelorism or broad forehead seen with GCPS. Imperforate anus and laryngeal clefts have been reported in PHS.[2, 10]
3. *Postaxial polydactyly A* (PAP-A). The third *GLI3* mutation causes PAP-A. This mutation lies further

Copyright © 2003, Mosby, Inc. All rights reserved.

downstream in the gene and causes truncation of the molecule after the microtubule-binding domain but before several hundred carboxy-terminal amino acids.[2]

TWIST TWIST is a basic helix-loop-helix type of nuclear transcription factor that is homologous to the *Drosophila* gene *twist*. In *Drosophila*, *twist* is involved with dorsoventral patterning and muscle differentiation. Both *twist* and FGFR are coexpressed in early mesoderm in *Drosophila*. TWIST appears to regulate the expression and activity of the FGFRs.[2] The Saethre-Chotzen syndrome is caused by missense, nonsense, and insertion-type mutations in the human TWIST gene. It may also arise, less often, by mutations in FGFR2 and FGFR3.[2] Mice with TWIST defects show the same craniofacial features as humans, plus reduplication of the first digit, an infrequent feature of Saethre-Chotzen syndrome in humans.[10]

MSX2 *MSX2* (muscle segment homeobox gene 2) is a homeotic gene situated at chromosome 5q34-q35. *MSX2* normally interacts with a transcription factor, TFIIF, which acts on DNA to promote transcription of other genes. In the normal person, this binding occurs over a limited period of time, leading to a finite amount of ''product.'' [326] In patients with Boston (type II) craniosynostosis and limb malformations, an autosomal dominant mutation substitutes histidine for a highly conserved proline (Pro148His) within the homeodomain of *MSX2* (Fig. 1-66). This substitution impedes proteolysis of the *MSX2* protein and affects the dissociation of (transcription-promoting) *MSX2* from DNA.[326] Reduced dissociation of *MSX2* from DNA leads to increased time of binding, increased production of the gene product, and the clinical syndrome. In mice, *MSX2* is expressed in the embryo, both in the calvarial sutures and in the distal portion of the limb bud during skeletal patterning. Transgenic mice that overexpress the wild-type molecule exhibit the same craniosynostosis as mice expressing the mutant form of *MSX2*.[2]

Relationship of Cranial Suture Morphogenesis and Craniosynostosis

In humans, cranial neural crest cells differentiate into primary and secondary cartilage, enchondral bone, and membranous bone and give rise to most of the skeletal tissues of the skull.[330] In the vault, mineralization proceeds outward from several ossification centers from about 13 wg on. At about 18 wg the mineralizing bone fronts meet, and sutures are induced along the lines of approximation. The skull subsequently enlarges by appositional growth at the suture, with deposition of unmineralized bone matrix (osteoid) along the suture margins.[328]

The suture is anatomically simple. Two plates of bone are separated by a narrow space that contains immature, rapidly dividing osteogenic stem cells. One portion of these stem cells is recruited to differentiate into osteoblasts and make new bone. The remainder resist differentiation into osteoblasts, continue to proliferate, and maintain the suture.[328] These events are partially controlled by *Fgfr1*, *Fgfr2*, *Fgfr3*, *MSX2*, and TGF-beta, which are expressed in the sutures. Premature fusion at one suture prevents further growth at that suture. Excessive growth at other sutures then leads to skull distortion.[328]

FGF 1, 2, and 3

FGF2 is a known survival factor for neural crest cells. Low concentrations of FGF2 cause concentration-dependent *proliferation* of osteogenic stem cells. High concentrations of FGF2 induce *osteoblastic skeletogenic differentiation* of these cells. Through an autoregulatory loop, high concentrations of FGF2 normally downregulate fgf2 to modulate the FGF2 concentration. FGF1 and FGF3 also play a role.[328, 330–332] The normal suture is maintained by a gradient of FGF2 that balances these signals, allowing osteogenic stem cells to proliferate in the center of the suture (where the concentrations of FGF2 are low) and to differentiate into osteoblasts at the margins of the sutures (i.e., at the edges of the growing calvarial plates), where the concentrations of FGF2 are higher (Fig. 1-67).

In mice, *Fgfr2* is expressed only in proliferating osteoprogenitor cells. Downregulation of *Fgfr2* and upregulation of *Fgfr1* signal the onset of differentiation into osteoblasts. Osteopontin, a marker of osteoblast differentiation, then appears, following which *Fgfr1* (plus osteonectin and alkaline phosphatase) become downregulated. *Fgfr3* is expressed both in osteogenic cells and in cranial cartilage, including a plate of cartilage that underlies the coronal suture.[331]

In mice, implantation of FGF2-soaked beads in the subcutaneous tissue over the coronal suture disrupts the normal suture and leads to synostosis. The local increase in the concentration of FGF2 causes three effects: (3) ectopic expression of *Fgfr1* and osteopontin (i.e., osteoblastic differentiation) in the sutural mesenchyme beneath the bead, (2) downregulation of *Fgfr2* locally (where the concentration of FGF2 is high), and (3) ectopic upregulation of *Fgfr2* in a ring surrounding the bead (where the concentration of FGF2 has fallen to a critical level around the circumference of the bead).[331] Since *low* levels of FGF2 maintain the proliferating population of osteogenic stem cells at the suture, and *high* levels of FGF2 stimulate osteoblastic differentiation, the *excessive* (constitutive ''on'') *FGFR2* signaling due to FGF mutations causes osteogenic differentiation and premature cranial synostosis.[328, 332]

The role of *MSX2* and TWIST, and their interaction with the FGFRs, is poorly understood. *MSX2* expression is associated with apoptosis in several cell types during development. Therefore, the craniosynostosis seen in *MSX2* patients could be due to abnormalities in the programmed death of connective tissue cells at the suture site. *MSX2* may participate in the FGFR signaling pathway, since it is coexpressed with FGFRs at the apical epidermal ridge of developing limbs and at the periphery of membranous calvarial bones. BMP signaling also regulates MSX expression, suggesting that this transcription factor may serve as a focal point for integrating multiple pathways that regulate skeletal development.[2]

In other species, *twist* is known to be a critical gene for mesoderm induction and to function later as a myogenic switch. Expression of specific fibroblast growth receptors depends on *twist.* Null mutants for such receptors show abnormal directions of cell migration and defective muscle formation.[328] Mesodermal expression of the *msh* gene is turned on later in myogenesis and is abolished in *twist* mutants. Similar effects could contribute to the abnormal suture development seen in TWIST mutants.[328]

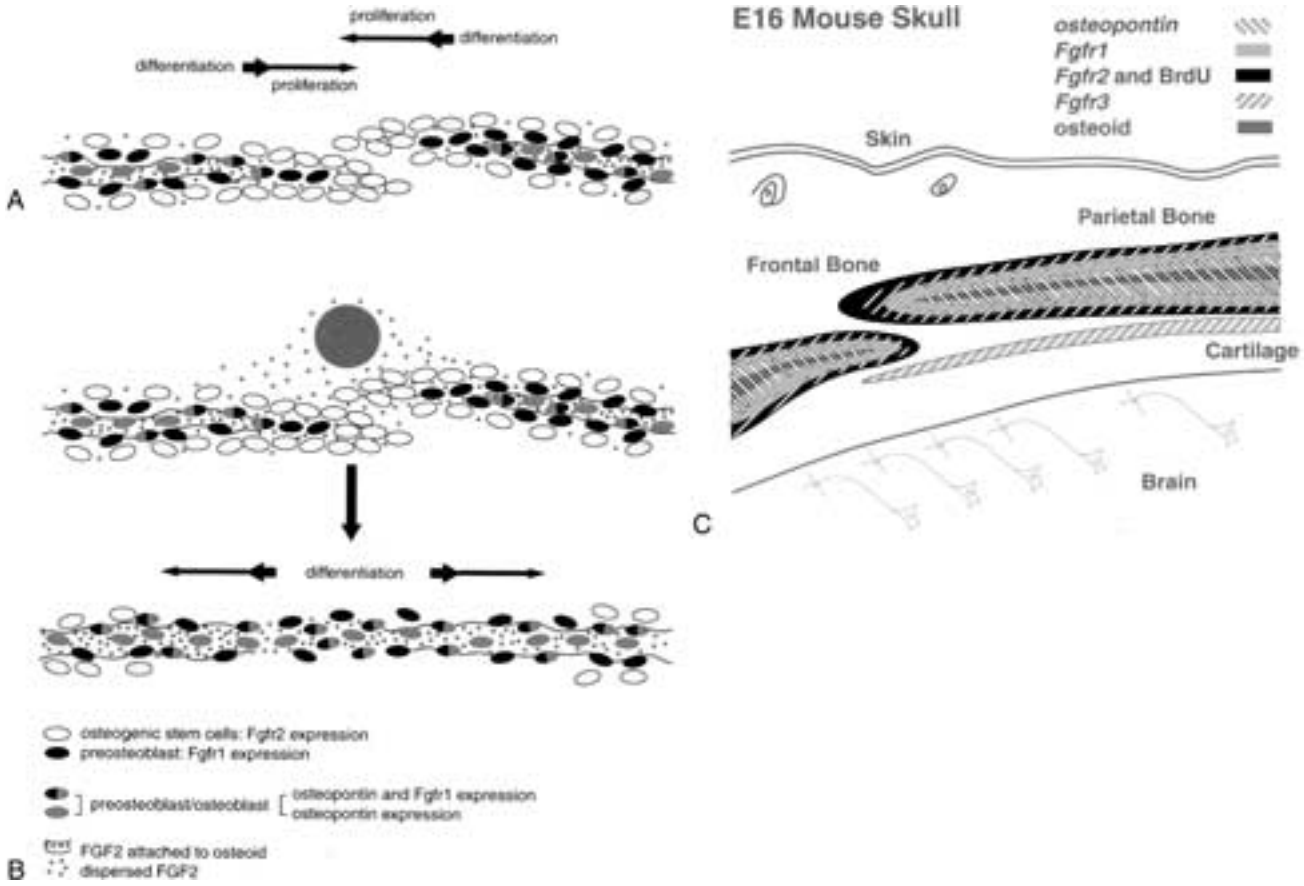

FIGURE 1-67 Molecular control of suture formation. **A** and **B**, Proposed model for the role of the FGFs and the FGFRs in balancing the proliferation and differentiation of osteogenic stem cells in the early fetal coronal suture of the mouse. **A**, Normal sutural growth. FGF2 is secreted by the osteoblasts. It is absorbed onto the unmineralized bone matrix. Lower levels of FGF2 diffuse into the extracellular environment of the sutural stem cells. These low levels of FGF2 stimulate the osteogenic stem cells to proliferate. These proliferating stem cells express *Fgfr2*. As new matrix is secreted by the differentiating cells, FGF2 levels rise in the environment of those osteogenic stem cells closest to the new matrix. The high levels of FGF2 stimulate these cells to differentiate into preosteoblasts. The process of differentiation involves downregulation of *Fgfr2*,exit from the cell cycle of proliferation, and subsequent upregulation of *Fgfr1*. Slightly later, there is upregulation of osteogenesis-related genes, including *osteopontin*. The preosteoblasts begin to secrete matrix and are then designated osteoblasts. *Fgfr1* is downregulated when differentiation is complete. **B**, Addition of ectopic FGF2 (*black circle* representing an FGF2-soaked bead) to the environment of the osteogenic stem cells raises the concentration of FGF2 locally and accelerates the process of differentiation, so the proliferating cell population is lost for the duration of the increased signal. This local increase in FGF2 mimics the effect of the gain-of-function, ''constitutively on'' mutations of FGFR1, FGFR2, and FGFR3 associated with the craniofacial dysostoses. **C**, Diagrammatic representation of the coronal suture of the fetal mouse. Summary of the expression patterns of the FGFR genes (*Fgfr 1, Fgfr2, and Fgfr3*) and of the osteogenesis-related gene *osteopontin*, a marker of osteoblast differentiation. *Fgfr2* is expressed only in proliferating osteogenic stem cells (osteoprogenitor cells). *Fgfr1* expression is associated with cell differentiation into osteoblasts. *Fgfr3* is expressed in both the osteogenic and chondrogenic portions of the skeletogenic membrane. The onset of differentiation toward osteoblasts is preceded by downregulation of *Fgfr2*, upregulation of *Fgrf1*, and upregulation of osteopontin. (From Iseki S, Wilkie AOM, Morriss-Kay GM. *Fgfr1* and *Fgfr2* have distinct differentiation- and proliferation-related roles in the developing mouse skull vault. Development 1999;126:5611–5620.)

Eponymous Craniosynostoses

Crouzon Syndrome

Crouzon syndrome (acrocephalosyndactyly type II) is the most frequent craniofacial dysostosis (1 per 25,000 births) (Figs. 1-65A, 1-68, and 1-69). It results from an autosomal dominant trait with variable expressivity. About 45% to 65% of cases are familial; the rest are sporadic.[308, 333] Clinically, Crouzon syndrome is characterized by bilateral coronal synostosis with a brachycephalic or oxycephalic vault. The sagittal and lambdoid sutures may also be affected. Typically, the sutures are not fused at birth but show progressive synostosis from about 1 year on.[308] Crouzon patients show maxillary hypoplasia with shallow orbits, bilateral exorbitism, and orbital hypertelorism. The nasal passages are partially obstructed, causing mouth breathing. *The hands and feet are spared*. Concurrent intracranial anomalies are common, including jugular venous obstruction with anomalous venous drainage (63%) and hydrocephalus. The hydrocephalus is more frequently progressive in Crouzon syndrome than in Apert syn-

FIGURE 1-68 Crouzon syndrome in a 9-year-old girl. **A** to **C**, Three-dimensional CT of the lateral skin surface (**A**), the lateral facial skeleton (**B**), and the frontal facial skeleton (**C**). **D**, Direct coronal CT. The patient shows oxycephaly, shallow orbits with exorbitism, hypoplasia of the midface with narrow, partially obstructed nasal passages, relative prognathism, and an everted lower lip.

drome.[208, 334] Chiari I malformation is seen in 71.4% of Cruzon patients.[208] Other features reported in Crouzon patients include calcification of the stylohyoid ligament (50% of patients older than 4 years), cervical spine anomalies, especially fusions of C2-C5 (up to 40%), elbow malformations (18%), minor hand deformities (10%), and visceral anomalies (7%).[208] Of all craniofacial dysostoses, the Cruzon patients with the FGFR3 mutation have the highest incidence of jugular venous stenosis or atresia and enlarged emissary veins. This phenomenon could reflect a relationship to the FGFR3 achondroplasia spectrum, which classically displays such venous stenoses and hydrocephalus.[335]

Apert Syndrome

Apert syndrome (acrocephalosyndactyly type I) is an autosomal dominant craniofacial dysostosis. Most cases arise sporadically as new mutations, but the disorder may be transmitted through families with complete penetrance. Apert syndrome occurs in 1 per 50,000 to 100,000 births, so it is less common than Crouzon syndrome. Clinically, Apert syndrome is characterized by severe symmetric syndactylism of the hands and feet. This is subclassified by the digits affected as type I (affecting digits 2, 3, and 4), type II (affecting digits 2, 3, 4, and 5), and type III (affecting all five digits).[308] Apert patients show bilateral coronal synostoses with brachycephaly, a midline defect due to widened metopic and sagittal sutures, orbital hypertelorism, shallow orbits with bilateral exorbitism, exotropia, maxillary hypoplasia with downturned mouth, high-arched palate, class III malocclusion, and anterior open bite (Figs. 1-65C,D and 1-70).[333] In Apert syndrome, the cranial changes appear to be more severe than those in Crouzon syndrome. The midface hypoplasia is present from birth. There is more severe redirection of the anterior cranial base and orbits, with greater brain compression and more prominent bulging of the eyes.

Cleft palate is present in 30% to 42% of Apert patients.[308] Choanal stenosis is common, but atresia is rare. Hypoplasia of the posterior choanae may compromise the nasopharyngeal and oropharyngeal airways, increasing the risk of respiratory distress, sleep apnea, cor pulmonale, and sudden death.[208] Eustachian tube dysfunction, otitis media, and conductive hearing loss are common. Sensorineural hearing loss is rare.[208] Apert patients show an increased incidence of callosal agenesis, megalencephaly, and gyral anomalies. Hydrocephalus may require shunt decompression before craniofacial surgery is performed. Most patients have normal intelligence but display specific learning difficulties. Up to one third suffer mental retardation. Approximately 70% show fusion of the cervical vertebrae, usually C5 and C6.[333] Rhizomelic shortening of the lower limbs reduces the stature by 5% to 50%.[307] There may be ankylosis of the elbows, hips, and shoulders. Concurrent problems with the cardiovascular (10%), genitourinary (9.6%), gastrointes-

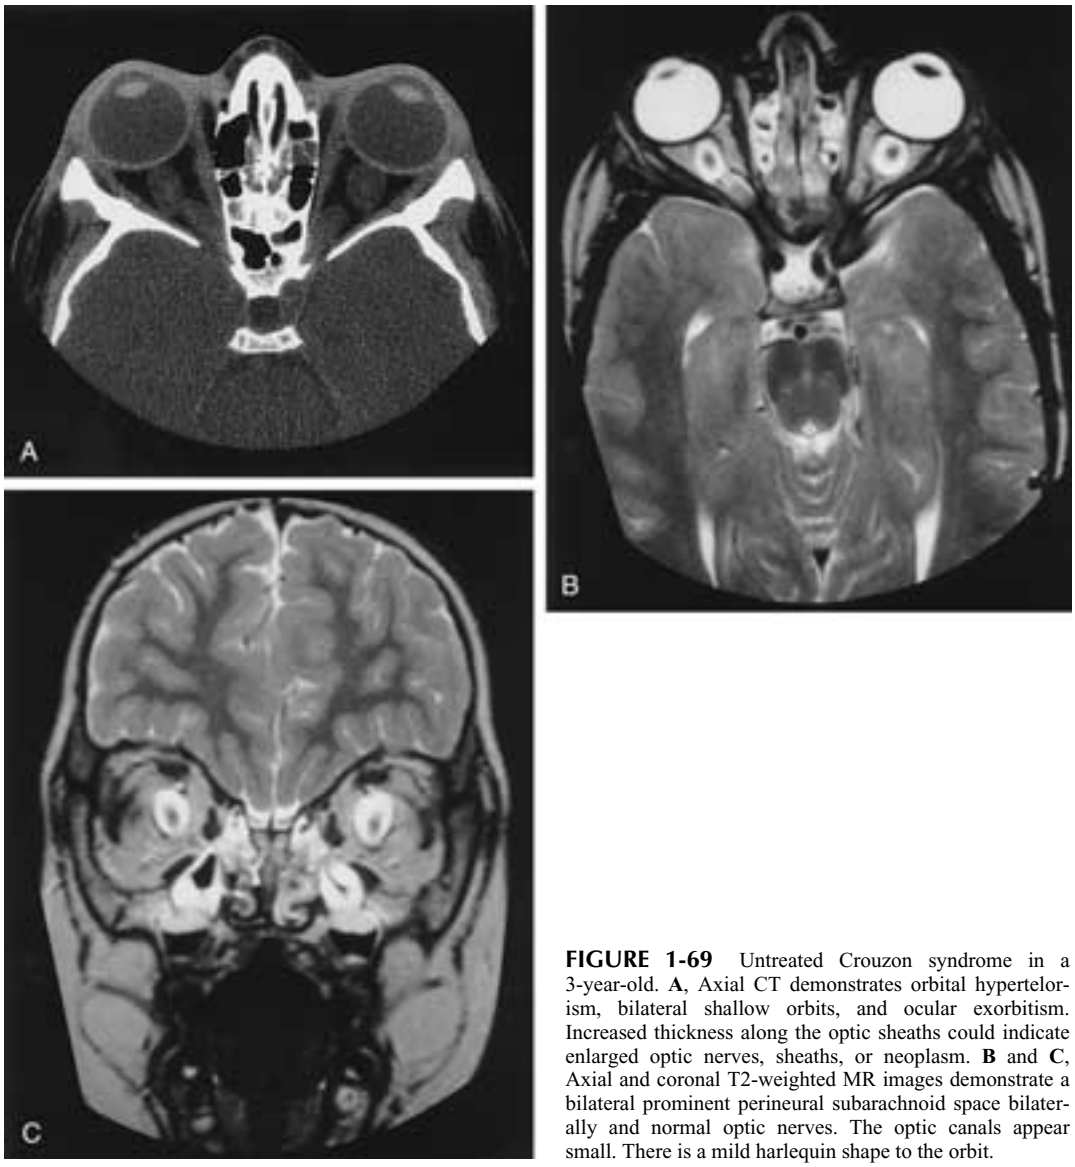

FIGURE 1-69 Untreated Crouzon syndrome in a 3-year-old. **A**, Axial CT demonstrates orbital hypertelorism, bilateral shallow orbits, and ocular exorbitism. Increased thickness along the optic sheaths could indicate enlarged optic nerves, sheaths, or neoplasm. **B** and **C**, Axial and coronal T2-weighted MR images demonstrate a bilateral prominent perineural subarachnoid space bilaterally and normal optic nerves. The optic canals appear small. There is a mild harlequin shape to the orbit.

tinal (1.5%), and respiratory (1.5%) systems contribute to patient morbidity.[208] The stylohyoid ligament may calcify in 38% to 88% of Apert patients.[208]

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome (acrocephalosyndactyly type III) is one of the more common craniofacial dysostoses, with an incidence of 1 per 50,000 to 1 per 100,000.[336] It is an autosomal dominant trait with complete penetrance (but variable phenotype) caused by mutations in TWIST, FGFR2, and FGFR3.[2] Saethre-Chotzen syndrome is characterized clinically by multiple suture synostoses with brachycephaly, hypertelorism with shallow orbits, maxillary hypoplasia, facial asymmetry, blepharoptosis, ear anomalies with prominent antihelical crura (crux cymbae), brachydactyly, and cutaneous syndactyly involving the second and third fingers (Fig. 1-65D,E).[326] Antimongoloid slant of the palpebral fissures, beaked nose, and a low-set frontal hairline are frequent. Increased intracranial pressure and mental retardation are infrequent.[326] The corresponding homozygous mutation causes cephalic neural tube defects and fetal lethality.

Pfeiffer Syndrome

Pfeiffer syndrome (acrocephalosyndactyly type V) is an autosomal dominant craniosynostosis with complete penetrance. It occurs in about 1 per 200,000 live births.[336] About 40% of the cases are familial, and 60% are sporadic.[308] Pfeiffer patients present clinically with soft-tissue syndactyly, broad great toes, broad thumbs, and radial deviation of the phalanges of the fingers (varus deformity). The head displays brachycephaly, short anterior fossa, receding lower forehead, supraorbital bar, hypertelorism, antimongoloid slant of the eyes, and flat nasal bridge.[307] The jaw is prognathic.[288, 326, 337] The clinical outcome of Pfeiffer patients varies widely, leading Cohen[338] to subclassify the disorder into three types. Type I is classic Pfeiffer syndrome, with a good clinical outcome. Type II shows severe concurrent CNS malformations with Kleeblattschädel and a poor prognosis. Type III shows severe CNS malformations without Kleeblattschädel, but still with a poor prognosis. Pfeiffer cases with Kleeblattschädel appear to map to FGFR2, while those with milder phenotypes generally map to FGFR1.[339]

Jackson-Weiss Syndrome

Jackson-Weiss syndrome is a clinically distinct autosomal dominant condition with craniosynostoses and concurrent foot anomalies.[333, 340, 341] The skull shape varies widely from brachycephaly to acrocephaly. Frontal prominence, hypertelorism, and strabismus have been noted. Intelligence is usually normal. The most consistent and distinctive feature of Jackson-Weiss syndrome is abnormality of the feet, with broad great toes, medial deviation of the toes, and tarsal-metatarsal coalitions. Hand anomalies are rare. There is great variability within families but high penetrance, so that some members have only foot deformities with no craniosynostosis.

Boston (Type 2) Craniosynostosis

Boston syndrome is an autosomal dominant condition localized to chromosome 5qter. It has a variable phenotype, including forehead retrusion, frontal bossing, turricephaly, and Kleeblattschädel. All affected individuals have recession in the supraorbital region in relation to the superior surface of the cornea. Most exhibit myopia or hyperopia.[326]

Muenke Syndrome

Muenke syndrome (Adelaide craniosynostosis) is an autosomal condition. Patients may show bicoronal synostosis (70%), unilateral coronal synostosis (30%), or simple macrocephaly.[333, 341] Muenke patients show midface hypoplasia (60%), downward slanting of the palpebral fissures (50%), strabismus and facial asymmetry (frequent), and sensorineural hearing loss (30%).[339] Broad halluces are seen clinically in 25%. Radiographs show short, broad middle phalanges in the hands but hypoplastic to absent middle phalanges in the toes.[339] Cone epiphyses are frequent in both hands and feet. Carpal and/or tarsal fusions are present in about 50%. Syndactyly and deviation of the great toes are not part of the syndrome.[339] A minority of Muenke patients show developmental delay.

Baere-Stevenson Cutis Gyrata Syndrome

The Baere-Stevenson syndrome is an extremely rare autosomal dominant form of craniosynostosis that leads to early death. Patients show Kleeblattschädel and severe dermatologic anomalies including corrugated skin furrows (cutis gyrata), extensive acanthosis nigricans, cutaneous or mucosal tags, and small nails. Other features include choanal atresia, bifid scrotum, and an enlarged umbilical stump. The mutation affects FGFR2, either in the transmembrane domain or in the extracellular domain at the linker region between the third Ig-like loop and the transmembrane domain.[339]

CONCLUSION

The broad spectrum of craniofacial malformations illustrates the differing ways in which basic embryologic mechanisms may deviate from the expected program.[342–344] Analysis of those malformations by molecular genetics is now providing increased understanding of the nature of those programs. Ultimately, it may be hoped that knowledge of the underlying mechanisms will allow us to tailor diets to meet the specific needs of each expectant mother to prevent these malformations and, at need, to call on the armamentarium of the body to effect scarless, seamless repair of any malformations that do occur.

INTRODUCTION TO THE SINONASAL CAVITIES

For most physicians, the ubiquitous nature of the allergic and infectious diseases that affect the paranasal sinuses and nasal cavities (sinonasal cavities) renders them the most often imaged and therefore the best known areas of the head and neck. In addition, facial fractures are common and range from the broken nose to the more severe complex fractures. Lastly, the disfiguring tumors of the sinonasal cavities have earned their fearsome reputation because of their poor prognosis and the facial carnage they wreak. It thus seems reasonable to start the discussion of head and neck imaging with the sinonasal region.

ANATOMY AND PHYSIOLOGY

The Nose and Nasal Fossae

The term *nose* usually refers to the external nose that projects ventral to the rest of the face, while the terms *nasal fossae* or *nasal cavities* refer to the internal nasal airways. Topographically the nose can be divided into subunits that have practical importance in reconstructive surgery.[1–6] These subunits consist of the nasal dorsum, nasal sidewalls, nasal tip and columella, alar lobule, and supraalar facets. The nasion is the junction of the root of the nose with the forehead, while the lower or caudal free margin of the nose is formed by the alar rim, columella, and tip. On either side, the lateral lower margin of the nose has an expanded, rounded area referred to as the alar lobule, which consists of skin and soft tissue posterior and inferior to the lateral crus of the lower lateral cartilage. The dorsum of the nose consists of the dorsum of the nasal bones superiorly and the dorsal border of the quadrangular cartilage with the medial attachments of the upper lateral cartilages inferiorly (Fig. 2-1). The bony-cartilaginous junction is called the rhinion. The junction of the alae with the face is known as the alar-facial junction.

The nose has an overall pyramidal shape. Superiorly on either side of the nose, the sidewall of the pyramid consists of the nasal bone and the ascending process of the maxilla with which it articulates. The nasal bones are narrower and thicker cranially where they articulate with the nasal process of the frontal bones. The posterior surface of the nasal bones in the midline articulates with the perpendicular plate of the ethmoid bone superiorly and the quadrangular cartilage of the nasal septum inferiorly. Caudally the nasal bones become wider and thinner. Inferiorly the nasal bones attach to and overlap the cephalic portion of the upper lateral cartilages. The bony pyramid thus stabilizes the upper lateral cartilages that form the inferior sidewall of the nasal cartilaginous pyramid.[1] Rarely, the nasal bones are fused in the midline or are absent and replaced by an elongated frontal process of the maxilla. The nasal bones are very infrequently multiple.

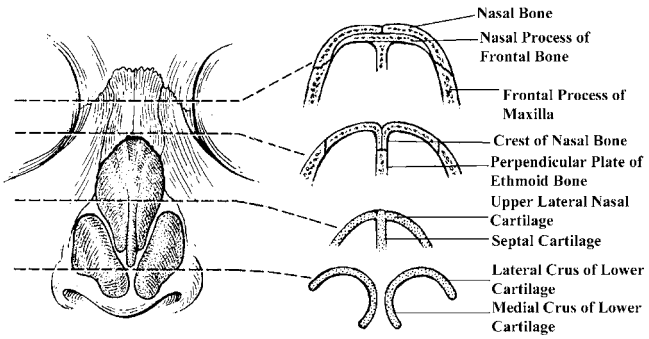

FIGURE 2-2 Frontal view of the nose with cross-sectional diagrams at various levels illustrating the support structure of the nasal pyramid. (Modified from Hollinshead H. Anatomy for Surgeons. The Head and Neck. Vol 1. New York, NY: Hoeber-Harper, 1954.)

VIEW IMAGE

The medial borders of the upper lateral cartilages are attached to the dorsum of the quadrangular cartilage of the septum and to each other. Laterally the upper lateral cartilages attach to the margin of the pyriform aperture (the osseous opening of the nasal cavity in the facial skeleton) by dense fibroareolar tissue. It is not uncommon to find accessory sesamoid cartilages in this area. The inferior border of the upper lateral cartilages are not attached and thus are mobile (Figs. 2-2 and 2-3).[2–5, 7]

On entering the nasal cavity, inspired air traverses the nasal valve. This is a circular area encompassed by the nasal septum, upper lateral cartilage, tip of the inferior turbinate, and floor of the nose. The total area encompassed by this valve provides the most important resistance to air flow in the nasal cavity.[8] Of slightly lesser importance is the angle formed by the meeting of the quadrangular cartilage of the nasal septum and the inferior border of the upper lateral cartilages, which is known as the nasal valve angle. Due to

its mobile nature, it is a dynamic structure that narrows and widens with the phases of respiration. It is thus a critical factor in determining airflow through the nasal cavity, and surgery in this area must preserve its integrity.

The lower paired lateral cartilages give the shape to the tip of the nose and base of the pyramid. Each lower lateral cartilage consists of medial crura and lateral crura. The point at which they meet dorsally is called the dome. The medial crura lie adjacent to the caudal end of the septum and attach to each other by loose connective tissue. At the dome, the lateral crura on either side extend superiorly and obliquely posteriorly toward the pyriform aperture, where they are attached by fibrous tissue. Sesamoid cartilages are also frequently found in this area of attachment. As each lateral crus extends superiorly, so does its lower border. The lower border thus does not parallel the alar rim. The soft tissue of the nose immediately below this area is devoid of cartilaginous support and is known as the alar lobule. The superior border of the lateral crus overlaps the distal ends of the upper lateral cartilages for a variable distance and is attached only by connective tissue. The skin covering the nose drapes across the angle formed at the junction of the medial and lateral crura, forming a triangular area called the facet (Figs. 2-2 and 2-3).

The nasal cavity on either side is separated by the nasal septum. The septum also helps support the bony and cartilaginous vault and the nasal tip. The main components of the nasal septum are the vomer, the perpendicular plate of the ethmoid, the quadrangular cartilage, the membranous septum, and the columella. Nasal bony crests from the upper surfaces of the palatine processes of the maxillae and the horizontal plates of the palatine bones also contribute to the inferior nasal septum (Fig. 2-4). The vomer may be bilaminar, due to its embryologic origin, and it and the perpendicular plate of the ethmoid bone are at times pneumatized. The perpendicular plate of the ethmoid fuses with the cribriform plate superiorly, and nasal septal surgery can cause a fracture of the cribriform plate, with a resultant cerebrospinal fluid leak. The vomer articulates superiorly with the perpendicular plate of the ethmoid and the crest of the sphenoid, anteriorly with the quadrangular cartilage, and inferiorly with the palatine bone and nasal crest of the maxilla. The vomer and quadrangular cartilage have a tongue-in-groove relationship with the thin edge of the cartilage, fitting into a groove of the vomer. The posterior border of the vomer is free and divides the posterior choanae (Fig. 2-4).

The quadrangular cartilage is the most important surgical component of the septum due to its supportive function, and it is that portion of the septum anterior to the pyriform aperture that is the most significant in this role.[1] Thus the portion of the septum that provides the principal support to the nose lies anterior to a line drawn from the rhinion to the nasal spine, and injury to this region can result in a saddle nose deformity. The septal cartilage has an unusually mobile articulation with the surrounding bones, with only connective tissue stabilizing this junction. This relationship allows mobility that minimizes the chance of fracture or dislocation.

The membranous septum is that portion of the septum that lies between the caudal end of the cartilaginous septum and the columella. It is comprised only of a core of subcutaneous tissue lined on either side by vestibular skin. The columella is the most inferior part of the septum, and it has as its central support the medial crus of the right and left lower lateral cartilages. The inferior border of the columella and the lower margin of the nasal alae form the boundaries of the nostrils or nares, which are the external openings of the nose and which provide entrance into the nasal fossae.

The nasal muscles are the procerus, nasalis (compressor naris including both transverse and alar parts), levator labii superioris alaeque nasi (part of the quadratus labii), depressor septi, and the anterior and posterior dilator naris. The procerus and the forehead muscles elevate the skin over the dorsum of the nose. The nasalis (both the transverse and the alar portions) compresses the nares, and the dilators and the levator superioris alaeque nasi dilate the nostrils (Fig. 2-5). The depressor septi draws the nasal tip downward. The importance of the nasal muscles can be demonstrated in seventh nerve paralysis, in which the resultant alar collapse leads to nasal obstruction (Table 2-1).

The nasal cavities, or nasal fossae, are separated in the midline by the nasal septum. Each cavity is roughly pear-shaped, being narrow above (cranially) and wide below (caudally). The roof is formed by the thin cribriform plate of the ethmoid, which is only 5 mm across at its widest

VIEW IMAGE

posterior margin. The floor of the nasal cavity is formed by the hard palate. The anterior two thirds of the hard palate is formed by the palatine processes of the maxillae, while the posterior one third is formed by the horizontal portions of the palatine bones.

The anterior portion of the nasal fossa that corresponds to the alar region of the nose is called the *vestibule*. It is lined with hair-bearing skin and sebaceous glands. Along the nasal septum there is no demarcation between the vestibule and the remaining nasal fossa. However, along the lateral wall there is a ridge, the limen vestibuli, that corresponds to the lower margin of the lateral crus of the cartilage, which marks the line of change from the skin of the vestibule into the mucous membrane of the remaining nasal fossa (Fig. 2-6).

The lateral wall of the nose is more intricate than the medial septal wall. Projecting from the lateral wall are three or four turbinates or conchae (Figs. 2-6 and 2-7). These conchae are scroll-like projections of bone that become smaller as they ascend the nasal cavity and that

Table 2-1
MUSCLES OF THE FACE

Muscle	Origin	Insertion	Innervation	Action
Procerus (pyramidalis nasi)	Fascia over lower nasal bone and upper lateral nasal cartilages	Skin between and above eyebrow	Facial nerve (VII) [T, lower Z, B]	Draws down medial angle of eyebrows Produces transverse wrinkles over bridge of nose
Compressor naris (nasalis)	Canine eminence near maxillary incisive fossa	Aponeurosis on nasal cartilages	Facial nerve (VII) [lower Z, B]	Draws ala of nose toward septum Compressor of nostrils
Depressor septi (depressor alae nasi)	Incisive fossa of maxilla	Septum and back of ala of nose	Facial nerve (VII) [Lower Z, B]	Narrows nostril, draws septum down
Dilator naris (anterior and posterior)	Margin of nasal notch of maxilla and lesser alar cartilage	Skin near margin of nostril	Facial nerve (VII) [Z, B]	Enlarges nasal aperture
Levator labii superioris (infraorbital head) and levator labii superioris alaeque nasi (angular head) zygomaticus minor (zygomatic head)	*Angular head* from upper frontal process of maxilla *Infra-orbital head* from margin of orbit near infraorbital foramen *Zygomatic head* from alar surface of zygoma	*Angular head* to greater alar cartilage, skin of nose, and lateral upper lip *Infraorbital head* into muscles of upper lip between angular head and caninus *Zygomatic head* into skin of nasolabial groove and upper lip	Facial nerve (VII) [Z, B]	*Angular head* elevates upper lip and dilates nostril *Infraorbital head* raises angle of mouth *Zygomatic head* elevates upper lip laterally
Zygomaticus (major)	Zygomatic portion of zygomatic arch	Angle of mouth and orbicularis oris, depressor anguli oris, and caninus	Facial nerve (VII) [Z, B]	Draws angle of mouth upward and backward (laughing)
Levator anguli oris (caninus)	Canine fossa of maxilla below infraorbital foramen	Into angle of mouth and muscles of orbicularis oris, depressor anguli oris, and zygomaticus	Facial nerve (VII) [Z, B]	Elevates angle of mouth
Risorius	Fascia over masseter superficial to platysma	Skin at angle of mandible	Facial nerve (VII) [Z, B]	Retracts angle of mouth (grinning)
Depressor labii inferioris (quadratus labii inferioris)	Lateral surface of mandible between symphysis and mental foramen	Skin of lower lip and orbicularis oris	Facial nerve (VII) [M, B]	Depresses lower lip and draws it laterally (irony)
Depressor anguli oris (triangularis) (in 50% of people) transverse menti part of triangularis	Continuous with platysma on oblique line of mandible	Angle of mouth into orbicularis oris and skin	Facial nerve (VII) [M, B]	Depresses angle of mouth, associated with grief

Table 2-1
MUSCLES OF THE FACE *Continued*

Muscle	Origin	Insertion	Innervation	Action
Mentalis	Incisive fossa of mandible	Skin of chin	Facial nerve (VII) [M]	Raises and protrudes lower lip, wrinkles skin, expresses doubt or disdain
Buccinator	Alveolar process of mandible opposite molar teeth and anterior border of the pterygomandibular raphe	Fibers converge toward angle of mouth where they blend with fibers of orbicularis oris muscle	Facial nerve (VII) [B]	Compresses cheeks, expels air from mouth, aids in chewing
Orbicularis oris	Sphincter muscle formed by contributions from various muscles and its own fibers Fibers from buccinator, levator anguli oris, depressor anguli oris, levator labii superioris, zygomaticus, depressor labii inferioris	Attaches to upper lip and lower lip, intermingles with fibers of origin, muscles, nasal septum	Facial nerve (VII) [lower Z, B, M]	Compression, contraction, and protrusion of lips. Involved in facial expression
Levator palpebrae superioris	Roof of orbit in front of optic foramen	Deep surface of upper eyelid, upper margin of superior tarsus, and superior fornix of conjunctiva	Cranial nerve III	Elevates eyelid voluntarily; attachment to superior tarsus acts involuntarily
Corrugater (supercilii)	Medial supraorbital	Skin of medial half of eyebrow	Facial nerve (VII) [Z, T]	Draws eyebrows downward and medially, produces wrinkles in frowning. Principal muscle in expression of suffering
Platysma	Fascia and skin over the upper part of the pectoralis and deltoid muscles	Lower border of the mandible and muscles of the lip	Facial nerve (VII) [C]	Produces a slight wrinkling of the skin surface of the neck, in an oblique direction, when entire muscle is brought into action. Anterior portion depresses the lower jaw and draws the lower lip and angles of the mouth down on each side
Oricularis oculi	*Orbital part* from medial orbital margin *Palpebral part* from palpebral ligament *Lacrimal part* from lacrimal bone	*Orbital fiber* arch around upper lid to lower lid and return to palpebral ligament *Palpebral fibers* go to *lacrimal fibers* to medial portion of upper and lower eyelids	Facial nerve (VII) [T, Z]	Sphincter of eyelids. The palpebral part is involuntary
Epicranius (occipitofrontalis)	Occipital bellies from lateral two thirds of superior nuchal line and mastoid process. Frontal bellies from epicranial aponeurosis at coronal suture	Skin of occipital region, skin of frontal region, and galea aponeurotica	Facial nerve (VII) [T, PA]	Moves scalp backward and forward, raises eyebrows (surprise)
Temporoparietalis	Temporal fascia above and anterior to the ear	Lateral border of the galea aponeurotica	Facial nerve (VII) [T]	Tightens scalp, draws back skin of temples
Auriculares (anterior, superior, posterior)	*Anterior:* temporal fascia and epicranial aponeurosis. *Superior:* epicranial aponeurosis and temporal fascia *Posterior:* mastoid process	*Anterior:* anterior and medial helix *Superior:* upper medial surface of auricle *Posterior:* Lower cranial surface of auricle	Facial nerve (VII) [T, PA]	Retracts and elevates ear

Branches of the facial nerve: B = buccal, C = cervical, M = mandibular, PA = posterior auricular, T = temporal, Z = zygomatic, lower Z = lower zygomatic.

are named respectively from inferiorly as the inferior, middle, superior, and supreme turbinates. The supreme turbinate is present in only 60% of cases. The air space beneath and lateral to each concha is called the meatus. The paranasal sinuses drain into the nose via these meati. The anatomy of the lateral nasal wall is discussed further in Chapter 3.

Physiology

There are three main physiologic functions of the nose: respiration, defense, and olfaction. In addition, a discussion of the physiology of the nose would not be complete without mention of the nasosystemic reflexes.

The nose plays an important role in respiration by

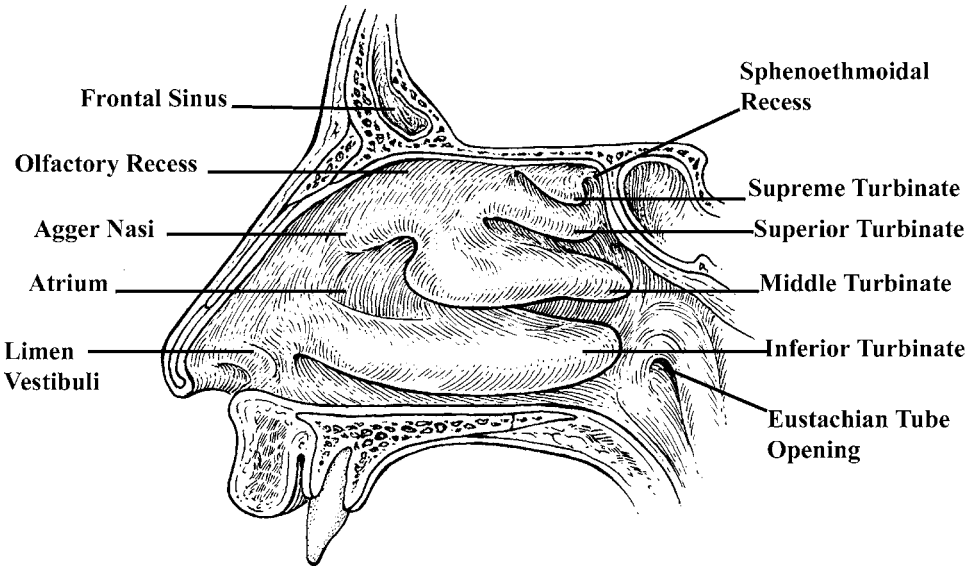

FIGURE 2-6 Diagram of a sagittal view of the lateral nasal fossa wall. The midline nasal septum has been removed.

VIEW IMAGE

effecting the nasal resistance and hence the airflow. The other effects of the nose on respiration are the humidification and warming of the inspired air.[8] In normal individuals with a tidal volume of <35 L/min, most respiratory airflow is nasal. Oral respiration is not physiologic and is a learned act that occurs during times of increased ventilatory demand.[9] This is well demonstrated in the case of newborns with bilateral choanal atresia, who, if not treated, would suffocate because they have not yet learned to breathe through their mouths.

Air enters the nares at an angle of 60° from the horizontal to reach the nasal valve, which has an area of only 0.32 cm^2. This is the most important factor contributing to nasal resistance and the resulting average airflow of 6.5 m/sec.[10] Once this point of resistance is passed, the nasal cross-sectional area increases with a decrease in airflow that results in turbulence. This turbulence is an important feature, as it allows increased contact of the air with the nasal mucosa. Once past the nasal valve area, the major airflow passes through the middle meatus. A lesser amount passes along the floor of the nose, and the least airflow is superiorly in the olfactory area.

Another modifier of nasal resistance is the dilator nasis muscle. This muscle dilates the nares, with a resultant decrease in resistance.[8] This becomes an important factor when increased ventilatory demand results in flaring of the nostrils.

Maintaining nasal resistance within certain limits is required for efficient pulmonary ventilation and gas exchange.[9] It should not be surprising that among the different factors affecting nasal resistance, two of the most important are hypoxia and hypercarbia, which decrease nasal resistance.[8]

The effect of gravity on the pooling of blood in the excessively vascular tissues over the turbinates leads to increased nasal resistance. This is commonly demonstrated by the observation in many patients that when they lie on one side, the dependent nasal chamber becomes progres-

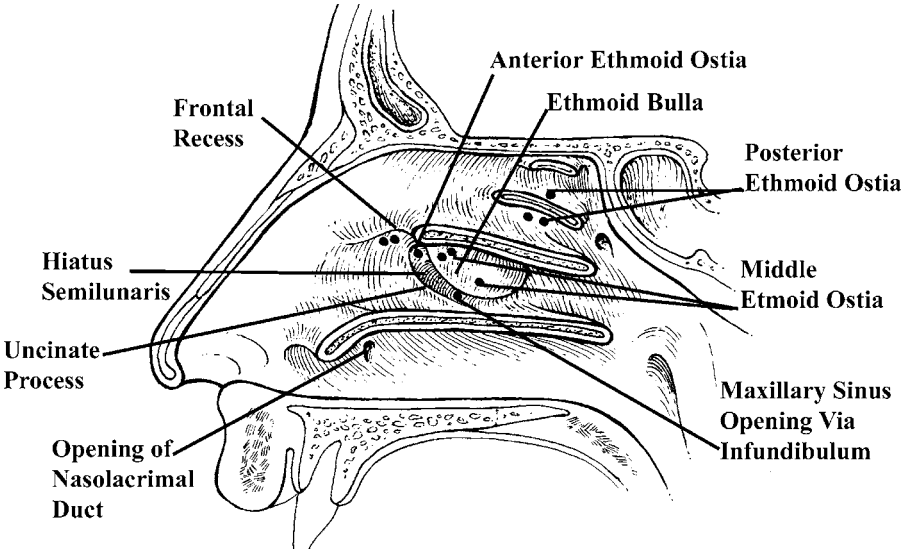

FIGURE 2-7 Diagram of a sagittal view of the lateral nasal fossa wall with the turbinates removed. The most common locations of the sinus ostia are indicated.

sively obstructed over a 15- to 20-minute period. When these patients turn to the opposite side, the clogged nasal fossa opens, and the dependent chamber becomes congested within 10 to 15 minutes.[7]

There are many other internal and external stimuli that affect nasal resistance by affecting the congestion of the nasal mucosa.[8] Some examples are vasomotor and allergic rhinitis, hormonal changes in pregnancy, thyroid dysfunction, and various medications. One phenomenon that affects nasal resistance is the nasal cycle. This occurs in 80% of individuals and results in one side of the nasal cavity being congested, with a decrease in serous and mucinous secretions, while the other side is decongested, with an increase in secretions.[8] The airflow through the nose is thus almost entirely through the patent side, and this alternates between the sides in a cyclical fashion every 1–4 hours. The function of the cycle is unclear; however, it can be documented on sectional imaging.[7] The appearance of the nasal cycle on imaging should not be confused with pathologic conditions.

Nasal resistance must be within certain limits; otherwise, the individual will have a subjective feeling of obstruction.[10] Thus the individual with a wide patent airway due to atrophic rhinitis or aggressive surgery will complain of nasal obstruction. When evaluating the cause of the patient's complaint, the clinician and radiologist should also be aware of the entity called paradoxical nasal obstruction. This situation occurs in patients who have learned to adapt to a long standing unilateral nasal obstruction.[8] The paradox exists because the patient complains of obstruction on the normal side when it becomes obstructed by congestion for various reasons, the most common being positional (with the normal side dependent), the nasal cycle, allergic rhinitis, or vasomotor rhinitis. The problem is corrected by directing treatment at the initially obstructed side.

Modification of the inspired air by humidification and warming are the other two main respiratory functions of the nose. The turbulent flow mentioned earlier allows the inspired air to interact over a large surface area.[10] Between 1 and 2 L of serous, watery secretions are produced daily by the serous glands of the nasal fossae, half of which is used to humidify inspired air.[11] The resultant nasal humidity is raised to 85%, which prevents drying of the lower airway and also enhances alveolar gas exchange.[8] Air entering the nose is efficiently warmed before reaching the lungs, and the average air temperature before entering the pharynx is 31 to 37° C . To perform this function, the average nose has about 160 cm^2 of mucous membrane, and the rich submucosal vasculature of the sidewalls of the nose makes an ideal surface for the conduction of heat to the air.[12]

The regulation of resistance, humidification, and temperature is performed by the specialized submucosal vascular network supplied by the autonomic nervous system.[13] There is a superficial capillary network that effects temperature change on the surface. At a deeper level there are venous lakes and sinuses that can produce changes in the thickness of the mucosa. Stimulation of the sympathetic nerves causes vasoconstriction, while stimulation of the parasympathetic system causes vasodilatation and nasal engorgement, with increased glandular secretions. The superficial mucosal vascular plexus works independently of the deep erectile vascular zone so that the surface temperature can vary independently of the patency or resistance of the airway. There are thus four major responses that the nasal tissue can give, depending on the nature of the inspired air: (1) hyperemia of surface vessels and filling of the erectile cavernous tissue in response to cold, dry air, (2) ischemia of the surface vessels and shrinkage of the erectile cavernous tissue in response to warm, moist air, (3) ischemia of the surface vessels and filling of the erectile cavernous tissue in response to warm air of average relative humidity, and (4) hyperemia of the surface vessels and shrinkage of the erectile cavernous tissue in response to superficial irritation.[3]

The second main function of the nose is one of defense. The mucosa of the nasal fossa is a vascular, pseudostratified columnar ciliated epithelium that contains both serous and mucinous glands. The term *Schneiderian membrane* is given to this mucosa, which is derived embryologically from the invaginating ectodermal nasal placodes. The mucosa lining the paranasal sinuses is very similar to that of the nasal mucosa except that it is less vascular, thinner, and more loosely attached to the bone. The mucosal surface is covered with a mucoid blanket that is serous around the cilia and mucoid on the remaining surface. This sticky layer is ideal for trapping particulate matter.[8] This surface film of mucus traps more than 95% of particulate matter larger than 4.5 μm. Thus the cilia beat in the lower viscosity layer, while the upper layer is transported by the motion of the tips of the cilia.[10] The coordinated ciliary action of the nasal mucosa prevents infection by propelling the mucus backward and downward into the nasopharynx at the rate of about 6.7 to 10 mm/min. The cilia beat at a rate of 160 to 1500 beats/min. The cilia function normally under most circumstances unless the mucous blanket is removed and drying occurs. Other factors can interfere with ciliary function, such as viral infection and topical decongestants. In these circumstances, cilial function is impaired.[12] The absence of ciliary movement leads to a stagnation of mucus, with the resultant necessity to frequently blow the nose and achieve postnasal clearing.[14] This movement of mucus is also affected by gravity and the traction that results from swallowing. It has been estimated that three fourths of the bacteria entering the nose are trapped by the mucus and that this nasal mucous blanket is renewed about every 10 to 20 minutes.[11] The normal nasal mucosa resists infection because the mucous blanket removes bacteria and some viruses before they can penetrate the mucosa. The mucus also contains antibacterial and antiviral substances such as lysozyme, interferon, and immunoglobulins (IgA, IgE, IgG) that are important defense mechanisms.

Olfaction occurs in the upper recesses of the nasal fossa. This region is bounded laterally by the superior nasal concha and the lateral nasal wall above this level, superiorly by the cribriform plate, and medially by a portion of the nasal septum. This olfactory epithelium is thicker (60 to 70 μm) than the surrounding respiratory epithelium (20 to 30 μm), and it covers an area approximately 1 cm^2 on each side. The epithelium is pseudostratified columnar and rests on a vascular lamina propria with no submucosa. There are four cell types in the olfactory mucosa.[2–5, 8] The first is the olfactory bipolar neuron which detects odors. The peripheral processes of these cells extend to the surface of the epithelium forming a tuft of olfactory hairs. The central

Copyright © 2003, Mosby, Inc. All rights reserved.

processes extend through the basal lamella to form a submucosal plexus that unites to form the 20 olfactory filia that pass through the cribriform plate. The bipolar neurons are replenished over a 7-week cycle. This is believed to be the only place in the body where special sensory cells are replaced after they die.[12] The remaining cells are microvillar cells whose function is still uncertain, supporting sustentacular cells, and basal cells that serve to replenish the bipolar cells. This mucosa has no ciliary action, and it is covered by a ''mucus'' that is derived from serous Bowman's glands deep in the lamina propria and from adjacent respiratory mucosal goblet cells. This mucous material spreads evenly over the surface of the olfactory epithelium, keeping it moist.

Although diffusion of odorants can provide access to the olfactory mucosa, the transport is facilitated by normal inhalation, and the most efficient transport of an odorant to the olfactory recess is accomplished by sniffing. Flavor, which is a combination of taste and smell, is thus affected if expired air does not reach the olfactory area.[14] The olfactory mucosa presents odorant molecules with certain constraints of absorption, solubility, and chemical reactivity.[12] Thus molecules may be perceived as being odorless for at least three reasons: (1) Their absorption by the mucus-lined respiratory nasal mucosal passages may be so high that all of the odorant is absorbed before it reaches the olfactory mucosa. (2) The molecules are not absorbed by the olfactory mucous secretions covering the olfactory mucosa and receptor cells. (3) A dried olfactory mucosa does not allow absorption, and thus there is no perception of smell.[3]

Once the odorant molecule reaches the receptor cell membrane, this molecule must alter the membrane potential of the olfactory receptor cell. The exact manner in which this is accomplished is not fully understood.[12] There are a number of theories of olfaction.[8] The molecular theory suggests that there are stereospecific receptors on the bipolar neurons. The temporal spatial theory suggests that the odor molecules are separated out in a manner that stimulates a specific area. Another theory claims that the odor molecules undergo some chemical reaction that depolarizes the bipolar cell. Regardless of which theory is correct, the ultimate event is depolarization of the bipolar cell, which results in a generator potential that leads to an action potential that travels along the first cranial nerve.

From the neuroepithelial receptor cells, fibers pass through the cribriform plate to terminate in the glomeruli of the olfactory bulb synapsing with the mitral and tufted cells that send their axons into the olfactory tract. The microcircuitry of these bulbs serves to narrow the spatial pattern of the glomerular inputs elicited by an odorant or a mixture of odorants.[12] From these bulbs, fibers then pass via the olfactory stria to medial and lateral septal nuclei situated just anterior and inferior to the rostrum of the corpus callosum. Then, from these septal nuclei, fibers pass into the limbic system, the uncus, the hippocampus, the parahippocampal region, the septum pellucidum, the fornices, the amygdala, and the gyrus rectus areas.[15] It has been noted that with orbitofrontal or medial thalamic lesions, odor discrimination and recognition are usually affected. However, in some cases, damage to these regions results in either no effect or an increased sensitivity to odor. It has also been noted that the recognition, interpretation, and memory of odors are located in the uncus and hippocampus, whereas the emotional response to odors is related to the entire limbic system.[15]

The maxillary division of the trigeminal nerve also plays a role in olfaction.[8] These nerve endings are sensitive to noxious stimuli such as ammonia. This can be used as a test for the malingering patient who feigns anosmia. The truly anosmic patient will respond to stimulation with ammonia, whereas the malingerer will deny it.

Olfaction is affected by the central processing of the messages from the olfactory area.[8] Clinically, olfactory cognition appears to develop between the ages of 3 and 5 years. Somewhere between the ages of 2 and 7 years, odor preferences are identified, and these are similar to those of adults living in the same area. That is, odors appear to be appreciated based upon individual experience and cultural restraints. It also appears that once an odor association is established, it is very difficult to erase it from memory and such an association may last for at least 1 year.[12] In humans, tests have shown that females have a better olfactory ability than males, both in threshold and in identification tasks.[12] In addition, olfaction is influenced by the menstrual cycle, being best at ovulation and poorest during menstruation. However, this effect is not simply hormonally related. Adaptation to odor also occurs so that the perception of an odor will fade if one is constantly exposed to it. This adaptation usually occurs within 5 minutes for chemical stimuli.

Abnormalities of the sense of smell include anosmia, which is the loss of the sense of smell; parosmia, which is a distortion or alteration of odors; and phantosmia, which is the usually constant perception of foul-smelling odors. Over 200 conditions have been associated with changes in olfaction, and these have been grouped into several categories.[12] The major categories associated with anosmia and the various percentages of occurrence from four major series are: (20% to 33%) obstructive nasal and sinus diseases (primarily nasal polyposis and chronic rhinitis), (15% to 32%) upper respiratory infection (URI) (persistent anosmia after the symptoms of the URI have resolved), and (9% to 32%) after head trauma (overall in adults, anosmia occurs in 5% to 10% of trauma cases, while in children transient anosmia occurs in 3.2% and permanent anosmia in 1.2%). Although frontal trauma most frequently causes anosmia, total anosmia is five times more likely after occipital trauma that results in a contra-coup shearing of the olfactory fibers) (0% to 8%) and with aging (More than half of the people 65 to 80 years old have a major decline in olfaction. This is also associated with Alzheimer's and Parkinson's diseases.), (0% to 8%) congenital (primarily familial anosmia and Kallmann's syndrome), (0% to 11%) toxic exposure (most toxins are either gases or aerosols), (8% to 16%) neoplasms (both sinonasal and intracranial tumors [25% of temporal lobe tumors are associated with olfactory disturbances]), (8% to 16%) psychiatric disorders (olfactory reference syndrome, Marcel Proust syndrome, etc.), parosmia and phantosmia (due to many causes, often associated with temporal lobe tumors or seizures), (0% to 26%) medications, (0% to 26%) surgery, and (0% to 26%) idiopathic causes (Table 2-2).[12]

The nasopulmonary and nasocardiac reflexes deserve mention.[8] The afferent pathway is via the maxillary division

of the trigeminal nerve. After central processing, the efferent pathway is via the vagus nerve to the various end organs including the heart, lungs, and vascular system. The effects include apnea, hyponea, bradycardia, cardiac arrhythmias, and a decrease in peripheral vascular resistance. These reflexes are responsible for those cases of hypoxia that can occur with posterior nasal packing. The high-risk patient should thus be closely monitored. Sneezing is also a reflex mediated via the trigeminal nerve. The resultant forceful expulsion of air is believed to be a basic protective mechanism.

Vascular Supply

The vascular supply of the nasal fossa involves both external and internal carotid arterial supplies. Of the five arteries that supply the nasal cavity, the sphenopalatine artery is the most important.[16] This artery originates from the third segment of the internal maxillary artery. It then exits the superomedial aspect of the pterygopalatine fossa by way of the sphenopalatine foramen. The sphenopalatine artery then enters the nasal fossa behind and slightly above the posterior end of the middle concha.

The sphenopalatine artery has two major branches, the posterior lateral nasal branches and the posterior septal branches. The posterior lateral nasal arteries ramify over the nasal conchae, first giving off branches that supply the inferior turbinate and then giving rise to superior branches that supply the middle and superior turbinates. These lateral nasal branches also assist in supplying the maxillary, ethmoid, and sphenoid sinuses.

After giving origin to the posterolateral nasal branches, the main trunk of the sphenopalatine artery continues medially across the face of the sphenoid sinus. When it reaches the nasal septum, the sphenopalatine artery gives off its medial branches, the posterior septal arteries. These branches course anteriorly along the nasal septum. The most inferior of these branches becomes the nasopalatine artery. This vessel runs through the incisive canal to anastomose with the greater palatine artery (Fig. 2-8).

The anterior and posterior ethmoidal arteries originate from the ophthalmic artery, which is a branch of the internal carotid. They enter the nasal cavity at the level of the cribriform plate (frontoethmoidal suture line via the anterior and posterior ethmoidal canals) to anastomose with nasal branches of the sphenopalatine artery. They are the only arteries in the body that run lateral to medial. This rich anastomotic network provides an important potential collateral pathway between the internal and external carotid circulations.

There are two other arteries that also provide some blood supply to the nasal fossa. The terminal branch of the greater palatine artery enters the incisive foramen, where it anastomoses with the nasopalatine artery (a septal branch of the sphenopalatine artery). The final artery supplying the nasal fossa is the septal branch of the superior labial artery. It originates from the facial artery and supplies the medial wall of the nasal vestibule (Table 2-3).

Little's, or Kiesselbach's, area is a localized region of the anteroinferior nasal septum (Fig. 2-8). It is supplied by branches of the facial, sphenopalatine, and greater palatine arteries. This is often referred to as Kiesselbach's plexus and is the site of 90% of the cases of epistaxis (Table 2-4).[4]

The venous drainage of the nose is via the anterior facial vein, the sphenopalatine vein, and the ethmoid veins. The anterior facial vein and ethmoid veins communicate with the ophthalmic veins, which drain directly into the cavernous sinus. The sphenopalatine vein enters the pterygoid plexus, which ultimately drains into the cavernous sinus. Thus intracranial complications such as meningitis, abscess, and cavernous sinus thrombosis can result from nasal and sinus infections.[13]

Table 2-3
ARTERIAL SUPPLY OF THE SINONASAL CAVITIES

External carotid artery ↓ Internal maxillary artery ↓ Sphenopalatine artery ↓ Posterior lateral nasal branches Posterior septal branches (anastomose with ethmoidal arteries) ↓ Nasopalatine artery (anastomoses with the greater palatine artery via incisive foramen)
Internal carotid artery ↓ Ophthalmic artery ↓ Anterior and posterior ethmoidal arteries (anastomose with nasal branches of the sphenopalatine artery)
External carotid artery ↓ Greater palatine artery enters the incisive foramen (anastomoses with the nasopalatine artery)
External carotid artery ↓ Facial artery ↓ Septal branch of the superior labial artery facial artery

↓ = artery gives off the following branch

The lymphatic drainage follows the veins rather than the arteries. The lymphatics of the anterior half of the nose drain across the face to enter the level IB nodes. The lymphatics of the posterior half of the nose and nasopharynx drain into the retropharyngeal nodes and levels II, III, IV, and V nodes.

Nerve Supply

The motor supply to the nasal respiratory muscles (the procerus, the nasalis, and the depressor septi nasi) is mediated through the seventh cranial nerve. The integration of their contraction with the respiratory cycle is with the tenth cranial nerve. The physiologically important control of the circulation and secretomotor function to the normal airway is mediated by the autonomic system, primarily via the sphenopalatine ganglion. Sympathetic stimulation results in a pale, dry, shrunken mucosa, and parasympathetic stimulation causes a hypersecreting, hyperemic, swollen mucosa. Pain, temperature, and touch are mediated by branches of the first and second divisions of the fifth cranial nerve.[11, 12, 17]

The sensory innervation of the nasal mucosa is by branches of the maxillary and ophthalmic division of the trigeminal nerve. In the pterygopalatine fossa, the maxillary nerve gives branches to the sphenopalatine ganglion. These sensory nerves traverse the ganglion without synapsing. The nasal branch of the sphenopalatine ganglion enters the nasal cavity through the sphenopalatine foramen and then divides into the lateral posterior superior and medial posterior superior branches. The lateral posterior superior branch supplies the superior and middle turbinates. The medial posterior superior branch crosses the face of the sphenoid to reach the nasal septum as the nasopalatine nerve. Anteriorly, this nerve extends through the incisive canal to supply the gingiva and mucosa posterior to the incisor teeth.[12] The lower part of the nasal cavity is supplied by the greater palatine branch of the sphenopalatine ganglion. In the greater palatine canal this nerve gives off branches that pass through the perpendicular plate of the palatine bone to reach the nasal wall and supply the inferior turbinate and adjacent inferior and middle meatus. The anterior portion of the nasal cavity is supplied by the ophthalmic division of V_2. After the ophthalmic division of the trigeminal nerve (V_1) enters the orbit, it gives off branches, among which is the nasociliary nerve. This nerve runs in the medial orbit and gives off the anterior and posterior ethmoidal nerves, which then exit the orbit through the anterior and posterior ethmoidal canals, where they innervate the ethmoid mucosa, the dura in the anterior cranial fossa, and the roof of the nasal cavity. The posterior ethmoidal nerve supplies a small area of mucosa near the superior concha on both the medial and lateral nasal walls. The anterior ethmoidal nerve supplies both the medial and lateral nasal fossa walls via its lateral and medial internal nasal branches.

Table 2-4
ARTERIAL SUPPLY TO KISSELBACH'S PLEXUS

Kiesselbach's plexus is supplied by branches of: The Facial artery The Sphenopalatine artery The Greater palatine artery

The autonomic innervation of the nasal fossa comes via the pterygopalatine (sphenopalatine) ganglion. Secretomotor (parasympathetic and motor) neural fibers originate in the brainstem at the nervous intermedius. These fibers run with the facial nerve to the geniculate ganglion, where they leave the facial nerve as the greater superficial petrosal nerve. This nerve runs along the anterior face of the petrous portion of the temporal bone to the cavernous sinus, where it receives sympathetic fibers from the deep petrosal nerve (originating from the cavernous portion of the internal carotid artery). The combined nerve then enters the vidian (pterygoid) canal as the vidian nerve, which goes to the pterygopalatine ganglion. The parasympathetic fibers synapse with postganglionic fibers in this ganglion and follow the branches of the trigeminal nerve to supply the nasal fossae and palatal region. The sympathetic fibers are already postganglionic, and thus they do not have synaptic connections in the sphenopalatine ganglion. They follow the blood vessels to supply the nasal fossae and palatal areas.[4, 6]

THE PARANASAL SINUSES

All of the paranasal sinuses originate as evaginations from the nasal fossae.[18] As such, they are lined by a mucosa that is similar to that found in the nasal cavity, which is a pseudostratified columnar ciliated epithelium that contains both mucinous (goblet cells) and serous glands. The nasal septum, by contrast, is lined by squamous mucosa with a paucity of minor salivary glands and a thinner, tightly tethered lamina propria. Because the mucosa of the paranasal sinuses is attached directly to the bone, it is frequently referred to as mucoperiosteum.[19] Although the mucoperiosteum of the sinuses is slightly thinner than the nasal mucosa, it is continuous with the nasal mucosa at the various sinus ostia.

The functional reason for the presence of the paranasal sinuses has been debated since the sinuses were first described in 1800. The paranasal sinuses have been thought

Copyright © 2003, Mosby, Inc. All rights reserved.

to contribute resonance to the voice, humidify and warm the inspired air, increase the olfactory membrane area, absorb shock to the face and head, provide thermal insulation for the brain, contribute to facial growth, represent vestigial structures, and lighten the skull and facial bones. Of these, the only documented reason appears to be that the paranasal sinuses form a collapsible framework that helps protect the brain from blunt trauma.[19] Also not understood are the reasons that cause some sinuses to be well developed, while others are hypoplastic. A question related to sinus growth is why some sinuses are routinely asymmetric.

Ethmoid Sinus

The ethmoid sinuses are divided into groups of cells by bony basal lamellae that extend laterally to the laminae papyracea and superiorly to the fovea ethmoidalis.[20] These lamellae serve as attachments for the turbinates. There are thus five lamellae, one for each of the primary turbinates (middle, superior, and occasionally the supreme) and one for each of the secondary turbinates (bullae ethmoidalis and uncinate process). In the adult, the lamella is not a straight bony partition. Instead, it is almost inseparable from the other ethmoid septa due to the lamella's being pushed and distorted from its original straight configuration in the fetal ethmoid bone by the other ethmoid air cells.[21] The basal lamella of the middle turbinate is the most important, as it divides the ethmoid into anterior and posterior groups of cells that drain into the middle and superior meati, respectively. In addition, the basal lamella only extends from the posterior portion of the middle turbinate, where it is attached to the lateral nasal wall. No basal lamella is present along the anterior portion of the middle turbinate.[22] Instead, it is replaced by a medial lamella that attaches to the lateral cribriform plate. The anterior ethmoid cells are more numerous and smaller, whereas the posterior cells are larger and fewer.[21] The adult ethmoid has 3 to 18 cells. The lamellae of the remaining turbinates further subdivide the anterior and posterior groups of cells.[20] Each group of cells drains into grooves that appear at intervals running diagonally posteriorly to inferiorly and parallel to the lamella. The classification of the cells is therefore based on the drainage site of their ostium. Thus the anterior ethmoid is subdivided into frontal recess cells draining into the frontal recess, infundibular cells draining into the infundibulum and hiatus semilunaris, and bullar cells draining into a groove on the bullae ethmoidalis called the *superior hiatus*. The posterior ethmoid is subdivided into posterior and postreme cells draining into the posterior and postreme meati, respectively. This drainage pattern is of clinical significance because one would expect all cells draining into one groove to be similarly infected. The ostia of the ethmoid sinuses are the smallest of all of the paranasal sinuses, measuring only 1 to 2 mm in diameter. Of these ostia, those of the anterior ethmoid cells are smaller than those of the posterior cells, a factor probably contributing to the higher incidence of anterior ethmoid mucoceles.[21]

The ethmoid sinuses begin to form in the third to fifth fetal months, when numerous separate evaginations arise from the nasal cavity. The anterior cells are the first to so form as evaginations in the lateral nasal wall in the region of the middle meatus. Posterior cell development follows as evaginations in the superior meatal area. The ethmoid sinuses expand at their own expense and at the expense of the other sinuses until puberty or until the sinus walls reach a layer of compact bone. The lamellae prevent one group of cells from intermingling with another, but they do not prevent intramural expansion of one group into another. A concha bullosa results when posterior ethmoid cells extend intramurally to pneumatize the middle turbinate. This can result in a large obstructing turbinate or a focus of infection. There can also be extramural expansion of ethmoid cells outside the ethmoid to invade the frontal, maxillary, and sphenoid sinuses as well as the ascending process of the maxilla and lacrimal bone. Encroaching cells are the rule, and one can find any pattern of intramural and extramural expansion, which should be considered normal variations and not anomalies.[20]

There are some specific patterns of extramural spread that are of clinical significance (see also the discussion in Chapter 3). Anterior ethmoid cells can pneumatize the frontal process of the maxilla adjacent to the anterior attachment of the middle turbinate to the ethmoid crest of the ascending process of the maxilla. These are known as the aggar nasi cells, and they are located in relationship to the lacrimal bone. When present, they are the most accessible part of the ethmoid intranasally.[23] Anterior ethmoid cells can also pneumatize the roof of the orbit as supraorbital ethmoid cells. Failure to recognize disease in such cells may lead to failure of operations on the frontal sinus. On coronal images, if a bony septum is seen separating the ethmoid complex from the recess in the roof of the orbit, then the recess comes from the frontal sinus and not from the supraorbital ethmoid cells (see atlas axial and coronal Fig. 2-1B). A posterior ethmoid cell can invade the medial floor of the orbit, resulting in a Haller cell. These cells can be a source of persistent infection if overlooked.[22] A posterior ethmoid cell can also invade the sphenoid bone. Such an extension is usually superior and lateral and is known as an Onodi cell if it is related to the optic nerve.[20] A posterior ethmoid cell can invade the maxilla. When it does, the extension is posterior to the maxillary sinus, causing a double antrum.[24] This must be recognized so that the posterior wall of the maxillary sinus is opened to gain access to infection in that cell.

At birth the anterior ethmoid complex is about 5 mm high, 2 mm long, and 2 mm wide. The posterior cell group is 5 mm high, 4 mm long, and 2 mm wide. The sinuses have virtually reached their adult size by age 12 years. In the adult the ethmoid labyrinth is pyramidal in shape, with its base directed posteriorly. The average dimensions are 4 to 5 cm long, 2.5 to 3 cm high, 0.5 cm wide anteriorly, and 1.5 cm wide posteriorly.[23] Less commonly, the ethmoid can attain a flat, thin form in which the anterior and posterior dimensions are the same. This is important to recognize since the operating space will not increase as you go posteriorly.

The ethmoid bone resembles a cross in coronal section.[21] The horizontal part is represented by the cribriform plate. The vertical portion above the cribriform consists of the cristae galli. Below the cribriform plate the vertical portion consists of the perpendicular plate of the ethmoid, which contributes to the nasal septum. Attached to the lateral end of each cribriform plate is the actual ethmoid labyrinth.

Copyright © 2003, Mosby, Inc. All rights reserved.

From an anatomic standpoint, it is best to look at the ethmoid labyrinth as a box.[21] The superior surface, or roof, of the ethmoid is related to the anterior cranial fossa. Mosher calls this the tragedy surface because in inexperienced hands the ethmoid operation is one of the easiest operations with which to kill a patient.[23] The roof of the ethmoid is actually formed by the orbital process of the frontal bone. The underlying ethmoid cells bulge into this, producing a pitted surface called the fovea ethmoidalis. The fovea ethmoidalis descends 15° as it extends posteriorly. Thus, anteriorly the fovea ethmoidalis can be as much as 4 to 7 mm higher than the cribriform plate to which it is attached. This results in a thin ascending lamella of bone joining the lateral border of the olfactory fissure to the fovea ethmoidalis. This bone is extremely thin and is more commonly the site of surgical injury than is the cribrifrom plate.

The lateral wall of the ethmoid is related to the orbit. The posterior two thirds of this surface is formed by the lamina papyracea that covers the posterior ethmoid cells. These cells are related to the orbital contents, optic nerve, and medial rectus muscle. The lamina papyracea articulates with the frontal bone superiorly, the maxilla inferiorly, and the lesser wing of the sphenoid posteriorly. The anterior and posterior ethmoid foramina lie along the frontoethmoidal suture line that is just below the dural line. Thus, if during an external ethmoidectomy a surgeon remains below a line connecting these foramina, the anterior cranial fossa should not be entered. The ethmoidal vessels and nerves pass into the ethmoid complex via these foramina. Dehiscences can occur in the lamina papyracea, and mild degrees of hypoplasia can result in a lateral concavity to the lamina papyracea. This also occasionally results in a wide beveled opening in the lamina papyracea where the anterior and posterior ethmoidal canals are located. The anterior one third of the lateral wall of the ethmoid is formed by the lacrimal bone that covers the anterior ethmoid cells. These cells are thus related to the lacrimal apparatus and orbital contents. The lacrimal bone is thus the major landmark to the anterior ethmoid cells when approached externally.[23] The posterior surface of the ethmoid is formed by the lateral two thirds of the anterior face of the sphenoid sinus. This will be discussed further in the section on the sphenoid sinus. The medial wall of each ethmoid labyrinth is the turbinate surface from which project the middle, superior, and (when present) supreme turbinates. As discussed earlier, the support for the turbinates is the basal lamella. The attachment of the basal lamella of the middle and superior turbinates to the lamina papyracea and fovea ethmoidalis marks the entrance of the anterior and posterior ethmoid arteries into the ethmoid sinuses.[21] The middle turbinate is of paramount importance in intranasal surgery. It attaches anteriorly to the ethmoid crest of the ascending process of the maxilla and posteriorly to the ethmoid crest of the palatine bone (which is just anterior to the sphenopalatine foramen). The posterior half of the middle turbinate is loosely attached to the body of the ethmoid bone by the basal lamella, and only the posterior tip is firmly attached to the lateral nasal wall at the ethmoid crest of the palatine bone.[22]

The anterior half of the middle turbinate is more complex. Mosher divides it into an upper part called the superior overhang and a lower part called the inferior overhang.[23] The division point is a line drawn forward from the upper end of the superior meatus. The inferior overhang is also known as the tip of the middle turbinate and is at a lower level than the anterior insertion of the middle turbinate. The portion of the lateral wall of the nose between the anterior insertion and the tip of the middle turbinate is known as the atrium. The medial or nasal surface of the superior overhang consists of a medial lamella that inserts into the skull base at the lateral margin of the cribriform plate.[22] It conducts olfactory fibers and is thus part of the olfactory area. In addition, it serves as a major surgical landmark to the cribriform plate and should always be preserved as a landmark during operations on the ethmoid. The middle turbinate covers two elevations on the medial wall of the ethmoid. The more prominent elevation is the bulla ethmoidalis, which is more posterior and superior. It is an accessory turbinate pneumatized by anterior bulla air cells. The more anterior inferior elevation is the uncinate process. It is also an accessory turbinate and originates from the anterior point of attachment of the middle turbinate. It then runs parallel to the bulla ethmoidalis in an inferior posterior direction. The anterior insertion of the uncinate process overlaps the lacrimal bone and nasolacrimal duct and is a useful guide to the location of the nasolacrimal duct. This explains how the nasolacrimal duct can be injured by coming too far anteriorly when one is performing an infundibulotomy or middle meatal antrotomy.

The groove formed between the bulla ethmoidalis and the uncinate process is called the hiatus semilunaris. The hiatus semilunaris extends laterally to open into the infundibulum, which is lateral to the uncinate process. The depth of the infundibulum is thus dictated by the height of the uncinate process.[25] Anterior infundibular cells and occasionally the frontal sinus open into the anterior portion of the infundibulum, whereas the maxillary sinus opens into the posterior portion of the infundibulum. The lacrimal bone sits on the lacrimal process of the inferior turbinate and articulates superiorly with the frontal bone. Its anterior half covers the nasolacrimal duct, whereas its posterior half is related to the anterior ethmoid cells. It is frequently pneumatized in series with the aggar nasi cells and serves as a landmark to the nasofrontal duct.

The superior turbinate lies above and posterior to the middle turbinate. Since it lies behind the basal lamella of the middle turbinate, it marks the medial wall of the posterior ethmoid cells. Its posterior end abuts the face of the sphenoid. Occasionally there is a supreme turbinate that lies above the superior turbinate and, when present, marks the most posterior ethmoid cells.

The inferior surface of the ethmoid is related to the medial portion of the roof of the maxillary antrum below. The hiatus semilunaris marks the inferior extent of the ethmoid intranasally.[23] Thus the superior half of the lateral wall of the nose is formed by the ethmoid and the inferior half by the medial wall of the maxillary sinus.

The anterior end of the ethmoid is related to the posterior surface of the ascending process of the maxilla. It is the only solid boundary of the labyrinth.[23] This is an important landmark, as it defines the location of the nasofrontal duct and nasolacrimal duct. Intranasally it is defined by a line joining the insertion of the middle turbinate to the insertion of the inferior turbinate. The lacrimal bone lies between this

ascending process of the maxilla and the anterior ethmoid cells.

The ethmoid sinuses receive their blood supply from nasal branches of the sphenopalatine artery and from the anterior and posterior ethmoidal arteries, which are branches of the ophthalmic artery. Thus the ethmoid sinuses receive blood from both the internal and external carotid arteries. The venous drainage is into the nose via the nasal veins or via the ethmoidal veins, which drain into the ophthalmic veins. This latter pathway is responsible for cavernous sinus thrombosis after ethmoid sinusitis. The sensory innervation of the ethmoid mucosa is via the ophthalmic and maxillary divisions of the trigeminal nerve. The nasociliary branch of the ophthalmic division supplies the anterior cells via the anterior ethmoidal nerve. The posterior ethmoid cells are supplied by the posterior ethmoidal nerve from the ophthalmic division and the posterolateral nasal branches of the sphenopalatine nerve from the maxillary division of the trigeminal nerve. The lymphatics drain into the submandibular lymph nodes (Level I nodes).[21, 26] The proximity of the posterior ethmoid cells to the orbital apex, optic canal, and optic nerve can lead to loss of vision as a complication of benign or malignant disease or surgery on these sinuses.

Frontal Sinus

The frontal sinuses arise from one of several outgrowths originating in the region of the frontal recess of the nose. Their site of origin can be identified on the mucosa as early as 3 to 4 months in utero. Less commonly, the frontal sinus develops from anterior ethmoid cells of the infundibulum. The frontal sinuses are in effect displaced anterior ethmoid cells, and because they develop from a variable site, their drainage will be either via an ostium into the frontal recess or via a nasofrontal duct into the anterior infundibulum.[18, 20] In any instance, the opening or duct can be distorted by expansion of adjacent ethmoid cells. As noted earlier, the location of the nasofrontal duct is marked intranasally by the insertion of the middle turbinate or aggar nasi cells if present. Dissection in this area will lead to the ascending process of the maxilla, which will lead to the nasofrontal duct. From an external approach, the lacrimal bone is the preferred landmark to the nasofrontal duct.[23] Once the lacrimal bone is entered, the dissection proceeds anteriorly to the ascending process of the maxilla and hence to the nasofrontal duct.

Because on the average the frontal sinuses do not reach up into the frontal bone until about the age of 6 years, these sinuses are essentially the only paranasal sinuses that are absent at birth. Their development is quite variable but effectively appears to start only after the second year of life.[27] In otherwise normal individuals, both frontal sinuses fail to develop in 4% of the population. If there is persistence of a metopic suture, the frontal sinuses are small or absent. On the average, by the age of 4 years, the cranial extent of the frontal sinus reaches half the height of the orbit, extending just above the top of the most anterior ethmoid cells. By the age of 8 years the top of the frontal sinuses is at the level of the orbital roof, and by the age of 10 years the sinuses extend into the vertical portion of the frontal bone. The final adult proportions are reached only after puberty.[4, 27]

Based on a study of 100 normal frontal sinuses, the area of a patient's frontal sinuses correlates well with two lines that can be drawn on either a plain film or a coronal CT scan. One line extends vertically from the level of the highest point of the orbital roof to the most cranial margin of the sinus. The other line extends from the base of the crista galli obliquely to the most lateral margin of the sinus. On a Franklin-type head unit or on CT, the maximum length of each line is 63 and 74.5 mm, respectively. If either of these lengths is exceeded, the sinus is larger than the 99th percentile of the normal population and is considered abnormally enlarged.[28] The average frontal sinus has been described as being 28 mm high, 24 mm wide, and 20 mm deep. However, there is a wide range in frontal sinus size, and the frontal pneumatization may involve the vertical plate (squamosal portion) of the frontal bone, the horizontal plate (orbital roof) of the frontal bone, or both of these areas. Recognition of an orbital recess to the frontal sinus is particularly important if frontal sinus obliterative surgery is to be performed. If only the vertical portion of the sinus is obliterated because an orbital recess was not identified preoperatively, a mucocele eventually develops in the obstructed orbital recess.

Because the frontal sinus develops from a variable site, in approximately 40% of cases it drains into the ethmoidal infundibulum. In this case, the ethmoidal infundibulum can act as a channel for carrying the secretions (and infection) from the frontal sinus to anterior ethmoid cells and the maxillary sinus or vice versa. It is primarily in the patient whose nasofrontal duct opens directly in the frontal recess or above the infundibulum (85% of cases) that the frontal sinus is accessible to intranasal cannulation. The natural frontal sinus ostium is usually located in the posteromedial floor of the sinus.

As mentioned, the factors responsible for determining the extent of frontal sinus growth are poorly understood. One of the factors implicated in influencing frontal sinus size is a relationship between the cessation of frontal lobe growth and the development of the frontal sinus. Frontal lobe expansion normally ceases its anterior growth by 7 years of age, at which time the inner table of the frontal bone stops its forward migration. Any further development of the frontal bone occurs secondary to anterior growth of the outer frontal table and sinus pneumatization. The ipsilateral frontal sinus is abnormally enlarged in patients with the Dyke-Davidoff-Masson syndrome with an underdeveloped hemicerebrum and in cases of early childhood damage to the frontal lobe.[29, 30] In addition, a direct relationship between the mechanical stresses of mastication and frontal sinus enlargement has been demonstrated, as has a direct relationship with growth hormone, as seen in acromegaly.[5, 30]

In some patients a frontal bulla develops. This is an upward displacement of the frontal sinus floor caused either by encroachment from the opposite frontal sinus or, more frequently, by an underlying ethmoid cell. This bulla may influence frontal sinus drainage, and it has been implicated as a cause of chronic frontal sinusitis in some patients.[4]

Each frontal sinus is a single cavity, although rare duplication of a sinus has been reported.[4] Usually the frontal sinuses are asymmetric in size. Often the larger sinus

Copyright © 2003, Mosby, Inc. All rights reserved.

extends across the midsagittal plane, so that a midline incision may inadvertently enter this sinus rather than the intended opposite smaller sinus. The normal sinus contour tends to be slightly scalloped, and intrasinus septa may extend into the sinus from one-half to one-third the height of the sinus cavity. Such septations can create recesses of the sinus that can be overlooked at surgery if preoperative imaging was not performed.

The larger the sinus cavity, the better the septations are developed. Conversely, in a hypoplastic frontal sinus, the sinus is usually a single, smoothly contoured cavity devoid of septations. As mentioned, the frontal sinus can pneumatize both the vertical and the horizontal (orbital) plates of the frontal bone. The deepest area of the vertical portion of the sinus is near the midline at the level of the supraorbital ridge, and the medial sinus floor and the caudal anterior sinus wall are thinnest in this area. As a result, the sinus is best approached for a trephination at this level. This thin anterior wall also permits the controlled fracture that is necessary in creating an osteoplastic flap of the frontal sinus.[21]

The intersinus septum is in reality the remaining frontal bone between the two frontal sinuses. It is usually in the midline at its base or lower portion; however, it may then deviate far to one side, depending on the differential growth rates of the frontal sinuses. Although the septum is almost always complete, focal areas of acquired or congenital dehiscence do occur, allowing intercommunication between the two frontal sinuses or herniation of the mucosa of one sinus into the contralateral sinus.[18] The normal well-developed frontal sinus abuts the superomedial orbital margin, but it does not encroach on the orbit and remodel it. Any flattening of this orbital margin should suggest the presence of an expanding frontal sinus process (mucocele, pneumocele, etc.).

Occasionally a central frontal sinus cavity is encountered, in the midline, just above the level of the nasion. This presumably is the result of a displaced ethmoid cell.

There is a rich sinus venous plexus (Breschet's canals) that communicates with both the diploic veins and the dural spaces. The main arterial supply to the frontal sinus is via the supraorbital and supratrochlear arteries derived from the ophthalmic artery. The venous drainage is primarily through the superior ophthalmic vein, and the sinus lymphatics drain across the face to the submandibular lymph nodes (level IB). The sensory innervation of the sinus mucosa is via the supraorbital and supratrochlear branches of the frontal nerve, which is a branch of the first division of the trigeminal nerve.

Sphenoid Sinus

The sphenoid sinuses emerge in the fourth fetal month as evaginations from the posterior nasal capsule into the sphenoid bone. This occurs just above small crescent-shaped ridges of bone, the sphenoidal conchae, that projects from the undersurface of the body of the sphenoid bone. These conchae grow forward, fusing with the posterior ethmoid labyrinth. Complete absence of the sphenoid sinus is rare. The degree of pneumatization, however, varies considerably. The sinus starts its major growth in the third to fifth year of life, and by age 7 years the sinus usually has extended posteriorly to the level of the anterior sella turcica wall. By the age of 10 to12 years the sinus usually has obtained its adult configuration.[20] The lack of any sinus pneumatization of the sphenoid bone by the age of 10 years should suggest the possibility of ''occult'' sphenoid bone pathology.[31] This is most commonly seen in diseases that require a large marrow demand to compensate for chronic anemia. Thus it is found in young patients with thalassemia and with chronic renal failure.

The average adult sphenoid sinus is 20 mm high, 23 mm long, and 17 mm wide. The posterior sinus development is variable. Depending on the degree of pneumatization, the sinus is classified as nonpneumatized, presellar, or sellar. In 60% of pneumatized sinuses, the sinus cavity extends posteriorly to the anterior sella turcica wall and lies under the sella floor (sellar). In 40% of sinuses, the sinus cavity extends only to the anterior wall of the sella turcica (presellar). In fewer than 1% of cases, the sphenoid sinuses do not develop posteriorly enough to reach the anterior sella wall (nonpneumatized). In this latter group of patients the thick, bony posterior sinus wall is a contraindication to transsphenoidal hypophysectomy.[32]

In 48% of people there are lateral recesses from the main sphenoid sinus cavity that extend into the greater sphenoid wing, where it forms the floor of the middle cranial fossa and the posterior orbital wall, the lesser sphenoid wing, or the pterygoid process. The pterygoid process is pneumatized in 25% of patients and is extensively pneumatized in 8% of patients.[33] It should be noted that there is considerable variation in the degree of pneumatization on the left and right sides of the sphenoid sinus. As a result of sphenoid pneumatization, the foramen rotundum may either be completely outside the sinus or bulge into the lower lateral sinus wall. Similarly, the vidian canal may either be within the sphenoid bone proper or elevated on a septum within the sinus cavity.

As mentioned earlier, the posterior ethmoid surface shares a common wall with the anterior face of the sphenoid sinus. The perpendicular attachment of the superior turbinate divides the face of the sphenoid into thirds.[23] The lateral two thirds form the common party wall with the posterior ethmoid cells. The medial one third of the sphenoid sinus's anterior wall is the free intranasal surface that is bounded by the superior turbinate laterally, the septum medially, the cribriform plate superiorly, and the upper surface of the posterior choanae inferiorly. The area bounded by the intranasal face of the sphenoid and the superior turbinate is called the sphenoethmoidal recess.[25] The ostia of the sinus is 2 to 3 mm in diameter and 2 to 5 mm from the midline and lies in the upper portion of the intranasal surface, 1.5 cm above the floor of the sinus. The normal drainage of each sphenoid sinus in the erect posture thus relies entirely on ciliary action. The ostium of the sphenoid can be located by passing a beaded probe 7 cm posterior to the anterior nasal spine upward at an angle of 30° to the floor of the nose.[34] The posterior wall of the sinus can lie up to 9 cm from the anterior nasal spine. If the probe goes beyond 9 cm, one must be concerned that the probe is intracranial. The sphenopalatine artery crosses the face of the sphenoid below the ostium. This must be cauterized or reflected inferiorly when approaching the sphenoid sinus.

The sphenoid sinus septum is usually in the midline ante-

Copyright © 2003, Mosby, Inc. All rights reserved.

riorly, aligned with the nasal septum. However, from this point it can deviate far to one side and even be twisted, creating two unequal sinus cavities. With the exception of the sinus roof, the other sinus walls are of variable thickness, depending on the degree of pneumatization. However, even in poorly developed sinuses the roof is thin, often measuring only 1 mm (planum sphenoidale). This wall is thus consistently vulnerable to perforation during surgery.

When the sphenoid sinuses are well developed, neighboring structures can be identified by their indentation into the sinus cavity. Thus, in addition to the already mentioned vidian or pterygoid canal and the foramen rotundum (maxillary nerve [V_2]), the optic nerve, the internal carotid artery, and the sphenopalatine ganglion all can be seen projecting toward the sinus cavity. Not only is knowledge of the anatomic relationships of the sphenoid sinus important because surgical complications may be avoided, but such knowledge can help explain unusual symptoms that arise from sphenoid sinus disease. Thus, from anteriorly to posteriorly, the sinus roof is related to the floor of the anterior cranial fossa, the optic chiasm, and the sella turcica. The lateral wall is related to the orbital apex, the optic canal, the optic nerve, the cavernous sinus, and the internal carotid artery. Situated posteriorly are the clivus, prepontine cistern, pons, and basilar artery. The sinus floor is the roof of the nasopharynx, and the anterior sinus wall is the back of the nasal fossa medially and the posterior ethmoid laterally. These anatomic relationships can present potential surgical hazards because fracture and removal of any sinus septations or indentations can lead to damage of the adjacent vessel or nerves. In addition, surgery in the sphenoid sinus can easily perforate the sinus walls and regions of the sphenoid sinus wall may be dehiscent.[35, 36] This is especially so with regard to the planum sphenoidale, the lateral sinus wall, and the medial roof of a lateral sinus recess into the greater sphenoid wing or pterygoid process. The latter area is frequently the site of spontaneous CSF leak into the sphenoid sinus, and in such cases this area should be carefully scrutinized.

There is a reciprocal relationship between the size of the sphenoid and the posterior ethmoid cells. When the posterior ethmoid invades the sphenoid it is usually in a posterior and superior direction, which will bring it into relationship with the optic nerve. It is thus important not to go further posteriorly than the face of the sphenoid when performing an ethmoidectomy. This can be accomplished by identifying the face of the sphenoid prior to performing the ethmoidectomy. The roof and lateral wall of the sphenoid sinus are continuous with the fovea ethmoidalis and laminae papyracea, respectively. Thus the sphenoid sinus is also an excellent surgical landmark from which to commence an intranasal ethmoidectomy.

The arterial supply of the sphenoid sinus is from branches of both the internal and external carotid arteries. The posterior ethmoidal branch of the ophthalmic artery may contribute vessels to the roof of the sphenoid sinus, and the floor of the sinus receives blood from the sphenopalatine branch of the maxillary artery. The venous drainage flows into the maxillary vein and the pterygoid venous plexus.

The sphenoid sinus is innervated from both the second and third divisions of the trigeminal nerve. The posterior ethmoid nerve from the nasociliary branch of the ophthalmic division supplies the roof of the sinus, and the sphenopalatine branches of the maxillary division supply the sinus floor.[36] The lymphatics drain into the retropharyngeal lymph nodes.[3]

Maxillary Sinus

The maxillary sinus is the first of the paranasal sinuses to form. At approximately the seventieth day of gestation, after each nasal fossa and its turbinates are established, a small ridge develops just above the inferior turbinate, marking the future uncinate process. Shortly after this, an evagination just above this ridge, the uncibullous groove, is seen, which then proceeds to enlarge laterally from the nasal cavity. This is the site of the original maxillary sinus bud. By birth a rudimentary sinus, measuring up to $7 \times 4 \times 4$ mm or, on the average, about 6 to 8 cm^3 is present, with its longest dimension in the anteroposterior axis.[21] The developing maxillary sinus initially lies medial to the orbit. The annual growth rate of the maxillary sinus is estimated to be 2 mm vertically and 3 mm anteroposteriorly.[37] By the end of the first year, the lateral margin of the sinus extends under the medial portion of the orbit. The sinus reaches the infraorbital canal by the second year and passes inferolaterally to it during the third and fourth years. By the ninth year the lateral sinus margin extends to the malar bone. Lateral growth ceases by the fifteenth year.

In infancy the maxillary sinus floor lies at the level of the middle meatus. By the eighth to ninth year the sinus floor is near the level of the nasal fossa floor.[38] From this point there is considerable variation in the further growth of the lower recess of the sinus. If the sinus continues to grow downward, it reaches the actual plane of the hard palate by age 12 years. The final descent of the sinus, signaling the cessation of sinus growth, is not complete until the third molar has erupted. In 20% of adults the most dependent portion of the maxillary sinus is above the nasal cavity floor. It lies at the same level as the nasal floor in 15% of adults and below this level in 65% of adults.[38] The mean dimensions of the adult maxillary sinus are 34 mm deep, 33 mm high, and 25 mm wide. The average volume of the adult maxillary sinus is 14.75 ml.

For the most part the maxillary sinuses develop symmetrically, with only minor common variations. Unilateral hypoplasia and bilateral hypoplasia occur in 1.7% and 7.2% of people, respectively.[39, 40] Hypoplasia of the maxilla results from trauma, infection, surgical intervention, or irradiation to the maxillary that occurs during the development of this bone. These conditions can damage the maxillary growth center, producing a small maxilla and thus a ''hypoplastic'' sinus. Underdevelopment also occurs in first and second branchial arch anomalies such as Treacher Collins syndrome, mandibulofacial dysostosis, and thalassemia major when the demand for marrow prohibits sinus pneumatization.

The maxillary sinus lies within the body of the maxillary bone. Behind the inferior orbital rim, each sinus roof, or orbital floor, slants obliquely upward so that the highest point of the sinus is in the posteromedial portion, lying directly beneath the orbital apex. The groove and canal for the maxillary nerve lie in the middle third of the sinus roof. About 1 cm behind the inferior orbital rim, the canal dives

Copyright © 2003, Mosby, Inc. All rights reserved.

downward to exit on the anterior face of the maxilla via the infraorbital foramen, which is about 1 cm below the inferior orbital rim. The medial antral wall is the inferolateral wall of the nasal cavity. The curved posterolateral wall separates the sinus from the infratemporal fossa. Each sinus has four recesses: the zygomatic recess, extending into the malar eminence or body of the zygoma; the palatine recess, which is usually small and variable, extending into the hard palate; the tuberosity recess, extending downward above and behind the third upper molar; and the alveolar recess, extending into the alveolar process of the maxilla. As discussed earlier, a posterior ethmoid cell can extend into the posterior maxilla and compartmentalize portions of the maxillary sinus. These uncommon septa usually divide the antrum into anterior and posterior sections, each of which may drain via accessory ostia into the nasal fossa. Rarely, a horizontal septum can divide the antrum into superior and inferior, or medial and lateral, portions.

The floor of the sinus is lowest near the second premolar and first molar teeth and usually lies 3 to 5 mm below the nasal floor. The roots of the three molar teeth often form conical elevations that project into the sinus floor. Less often the roots of the premolar and, even more rarely, the canine teeth project into the antrum. Occasionally there is dehiscent bone over the tooth roots, so that only sinus mucosa covers these roots and separates them from the main sinus cavity.[21] The lower expansion of the antrum is intimately related to dentition; when a tooth erupts, the vacated space becomes pneumatized, thus expanding the sinus lumen.

In the adult disarticulated skull the medial wall of the maxillary bone has a large hole, the maxillary hiatus, that exposes the interior of the maxillary sinus. However, in life, or in an articulated skull, this hole is partially covered by portions of four bones.[24] In addition to the portions of the ethmoid bone (to be discussed further), the perpendicular plate of the palatine bone covers part of the posterior maxillary hiatus, while the lacrimal bone covers the anterior and superior regions.

The inferior turbinate covers the inferior portion of the maxillary hiatus. It attaches anteriorly to the conchal crest of the ascending process of the maxilla and posteriorly to the conchal crest of the palatine bone. It has a thin maxillary process that articulates with the inferior rim of the maxillary hiatus. When performing an inferior meatal antrostomy, it is thus easier to enter the maxillary sinus through this thin bone in the upper part of the inferior meatus rather than through the thick bone of the maxilla in the lower part of the meatus. When performing an inferior meatal antrostomy, it is important to remember that the nasolacrimal duct terminates in the anterior superior portion of the inferior meatus.

The ethmoid bone is the last bone to help close the maxillary hiatus, as it rests above the line of attachment of the inferior turbinate as the uncinate process and ethmoid labyrinth. Below the uncinate process, the medial maxillary hiatus is covered by the opposing nasal and sinus mucosa. This membranous area is called the fontanelle. It is divided into a posterior and an anterior fontanelle by the ethmoidal process of the inferior turbinate, which extends superiorly to contact the uncinate process. This membranous area can break down secondary to infection, with the resultant formation of accessory ostia. In addition, this area of the middle meatus can be safely penetrated when the natural maxillary ostium cannot be clinically cannulated because of a large uncinate process or when it is believed that the orbit is at risk.[21] Above the uncinate process is the hiatus semilunaris and the remainder of the ethmoid labyrinth. The ostium of the maxillary sinus is on the highest part of the medial sinus wall and can be up to 4 mm in diameter. It does not open directly into the nasal fossa but rather into the posterior portion of the ethmoidal infundibulum, which, via the hiatus semilunaris, opens into the nasal cavity. The channel of the infundibulum is approximately 5 mm long and is directed upward and medially into the nasal fossa. The sinus ostial location dictates that sinus drainage in the erect position is accomplished by intact ciliary action. Thus a narrow infundibulum can interfere further with sinus drainage.

The location of the sinus ostium can be variable. When high, it lies just below the orbital floor. The ostium can also open further anteriorly in the infundibulum, bringing it even closer to the orbit. Thus, depending on the situation, the surgeon may elect to enter the maxillary sinus at a lower level such as the membranous fontanelle, as discussed earlier.

The maxillary sinus is vascularized via branches of the maxillary artery, and the supply is essentially topographic. Thus the infraorbital, greater palatine, posterosuperior alveolar, and anterosuperior alveolar arteries all contribute a blood supply. In addition, there are lateral nasal branches of the sphenopalatine artery and a small contribution from the facial artery. The venous drainage is anteriorly via the anterior facial vein and posteriorly via the maxillary vein. The maxillary vein joins the superficial temporal vein to form the retromandibular (posterior facial) vein, which drains into the jugular vein. However, the maxillary vein also communicates with the pterygoid venous plexus, which anastomoses with the dural sinuses through the skull base. It is through this latter pathway that maxillary sinusitis can lead to meningitis.[36]

The nerve supply to the antrum is via branches of the second division of the trigeminal nerve, namely, the branches of the superior alveolar nerves (posterior, middle, anterior), the anterior palatine nerve, and the infraorbital nerve. Of these, the posterior superior alveolar nerve pierces the posterior antral wall and runs forward and downward in a small canal to supply the molar teeth. The lymphatics of the main sinus drain into the lateral retropharyngeal and internal jugular nodes (levels II, III, and IV), and those of the lateral portion of the antrum drain into the submandibular nodes (level IB).

PLAIN FILMS

In the present-day environment of emergency room medicine, there has been a resurgence of the use of plain film radiographs of the paranasal sinuses. In part this reflects their comparatively low cost, low radiation dose, and ready availability. These plain film studies are either the initial and only imaging study or, if clinically indicated, they may be followed by computed tomographic (CT) and/or magnetic resonance (MR) imaging studies. There are a number of plain film radiographic views available for evaluating the paranasal sinuses; however, only four of these projections

Copyright © 2003, Mosby, Inc. All rights reserved.

are routinely employed. These consist of two frontal projections—the Caldwell and the Waters views—a base (submentovertex) view, and a lateral view. The most popular of the additional views include the oblique projection (Rhese view), other craniocaudal angulations of the frontal projection (transorbital, posteroanterior projections), the Towne view, the Granger view, and the modified Waters view.[27, 41]

If possible, the plain film examination should be performed with the patient sitting or standing erect so that any air-fluid levels can be clearly identified. If the patient cannot tolerate erect positioning, a cross-table lateral film with a horizontal beam should be obtained to visualize any potential air-fluid levels. If neither of these approaches can be used, on either supine or prone films any free sinus fluid will layer on the dependent sinus wall, and the sinus will

PLAIN FILM VIEWS

Horizontal Beam 5° Off-Lateral View

To achieve the horizontal beam 5° off-lateral view, the patient's head is positioned laterally relative to the cassette, and the nose is then rotated 5° toward the cassette from the true lateral position. If the patient is seated, the cassette is usually placed in the vertical position. If the patient is lying down in either the semiprone or the prone position, the cassette is positioned horizontally. The central ray enters perpendicular to the cassette and is centered at the outer canthus of the eye in the middle of the film. The orbitomeatal line is parallel to the base of the film (Fig. 2-9). The purpose of using the 5° off-lateral view rather than the true lateral view is to rotate the posterior walls of the maxillary antra slightly so that they do not superimpose on one another. This permits individual evaluation of the integrity of the posterior antral bony margins.

Modified Caldwell View

For the modified Caldwell view, the patient is positioned directly facing the cassette in either the sitting or the prone position. The midsagittal plane is perpendicular to the film. The orbitomeatal line is perpendicular to the cassette, and the central ray is angled 15° caudally as it enters the posterior skull. The central ray also serves as the centering point of the skull on the cassette. If the patient is properly positioned, this view projects the petrous pyramids in the lower third of the orbits (Fig. 2-10). The Caldwell view is the best projection for examining the frontal and ethmoid sinuses in the frontal projection.

Modified Waters View

For the modified Waters view, the patient is positioned facing the cassette in either the erect or the prone position. The orbitomeatal line is angled 37° to the plane of the cassette. The central ray is centered on the film perpendicu-

VIEW IMAGE

lar to the cassette, emerging at the anterior nasal spine of the patient (Fig. 2-11A,B).

Variations in the positioning angle may be required to give the ''perfect'' Waters view. On the one hand, if the head is not sufficiently extended, the petrous pyramids are projected over the maxillary sinuses, thereby obscuring sinus detail. On the other hand, if the head is hyperextended, the maxillary sinuses become distorted and foreshortened, thus obscuring sinus disease. The ''perfect'' Waters view has the petrous pyramids projected just below the floor of the sinus cavities. This is the best single view for the evaluation of the maxillary antra in the frontal projection. Another variation is to use the Mahoney modification with the mouth open.[41] The open-mouth Waters view normally allows good visualization of the lower posterior sphenoid sinus margins (Fig. 2-11C).

Modified Base (Submentovertical or Submentovertex) View

The modified base view was described by Schuller and Pfeiffer.[41] The reference line used is the infraorbital line, which runs from the infraorbital margin to the center of the external auditory meatus. The goal of the positioning is to have the infraorbitomeatal line parallel to the film plane. This projection is considerably easier to obtain with the patient in either the sitting (erect) or the prone position. Patients with cervical or thoracic degenerative disease, those with a short neck, or those who are obese have difficulty extending the head sufficiently if the examination is attempted with the patient supine. The central ray is directed perpendicular to the infraorbitomeatal line and centered 1 inch anteriorly to the plane of the external auditory meatus (Fig. 2-12). A modification, with the centering 1½ inches in front of the external auditory meatus, has also been suggested.

A variation of the traditional submentovertex view is the Welin, or overangulated base, view. This view results in an average angle of 120° open posteriorly between the infraorbitomeatal line and the cassette. This overangulation is accomplished by tilting the top of the cassette toward the patient while the patient's head is fully extended, as in the modified base projection. The central ray is directed to the level of the frontal sinus. This position provides a useful adjunct view for evaluation of the anterior and posterior walls of the frontal sinuses (Fig. 2-13). It is also a good view for evaluating the lateral and, to a lesser extent, the medial walls of the maxillary antra. The sphenoid and ethmoid sinuses, with the nasal cavity superimposed, are thrown into relief with this projection.

Rhese or Oblique View

The Rhese view is excellent for studying the posterior ethmoid air cells, which are otherwise obscured by superimposition of the anterior cells in the frontal views. Superimposition of the anterior right and left ethmoid cells in the Rhese view, however, tends to limit its usefulness in paranasal sinus examination. Correct positioning places the optic canal just off the midorbit in the lower outer quadrant. Each side is imaged separately, and then the images are compared. The patient is placed in either the seated erect

Copyright © 2003, Mosby, Inc. All rights reserved.

position or the prone position. Then the median sagittal plane of the body is centered with the midline of the cassette. With the orbit centered in the portion of the cassette to be used, the flexion of the head is adjusted so that the canthomeatal line is perpendicular to the film. The patient's head is rotated so that the median sagittal plane forms an angle of 53° with the plane of the film. The central ray enters the skull posteriorly at an angle of 15° with the canthomeatal line and emerges at the midorbit (Fig. 2-14).[41] Short of sectional imaging, the oblique views coupled with a Caldwell view provide the least obscured images of the ethmoid cells.

Nasal Bone Lateral View

To achieve the nasal bone lateral view, the patient is usually placed in a semiprone position, with the body rotated so that the median sagittal plane of the head is horizontal and parallel to the plane of the tabletop. The interpupillary line is also perpendicular to this plane. The flexion of the head ought to be such that the orbitomeatal line is parallel with the transverse axis at the tabletop. The jaw should be supported with a sandbag to prevent rotation. The film is placed under the frontonasal region and centered at the nasion. The focal-film distance should be 36 inches (Fig. 2-15).

VIEW IMAGE

FIGURE 2-12 Modified base view. **A**, Positioning diagram. **B**, Sample radiograph.

Nasal Bone Axial View

The success of the nasal bone axial projection depends on either having the patient hold the occlusal film correctly between the front teeth or placing the larger film cassette under the patient's chin so that the plane of the film is at right angles to the glabelloalveolar line. The central ray should be directed along this line at right angles to the plane of the film (Fig. 2-16).

IMAGING ANATOMY

Despite the most meticulous attention to technical detail, plain film examinations have substantial limitations. That is, even if interpreted by a knowledgeable radiologist, the full degree of both soft-tissue and bone disease may be consistently underestimated. In response to this limitation, in the recent decade and a half it has become popular to perform limited, low-cost, low-dose, coronal CT studies as

an alternative to the plain film examination. Although the radiation dose of these limited CT studies is lower than that of the routine CT examination, it usually is higher than that of a plain film series. This radiation dose and the frequency of these examinations represent a net radiation risk to the population. Thus the clinical setting for these studies should be carefully monitored so that patient dose and examination cost are balanced by the radiologist's choice of the best study to provide the information needed by the clinician determining the patient's management.

Patients who have signs and symptoms of acute sinonasal disease usually do not require any radiologic study, as most often they respond to conservative medical management. If the clinician is concerned that obstruction to sinus emptying has occurred, an erect plain film study will provide good visualization of any air-fluid level. The plain film examination also provides a gross assessment of sinus disease, usually all the information that is needed by the clinician at this initial stage of assessment. However, if the patient has associated signs or symptoms that suggest extension of disease outside the boundaries of the sinonasal cavities, a more detailed examination such as either a contrast-enhanced CT scan or an MR imaging study should be performed to provide better disease mapping. Signs or symptoms that should signal CT or MR imaging include headache, retro-orbital pain, orbital pain, suboccipital pain, facial swelling, orbital inflammatory disease, and proptosis.

It is estimated that between one third and one half of patients with acute sinonasal inflammatory disease will progress to chronic disease. In these cases, it is probable that some type of surgical intervention will be a part of further treatment, and a preoperative CT scan should be obtained. Not only is disease mapping more complete on CT scans than on plain films, but normal anatomic variants can be identified that may influence surgery or aid the surgeon in avoiding an operative complication. That is, if sinus surgery is planned, a plain film examination can not only be avoided, but it should be considered inadequate as a preoperative study.

Copyright © 2003, Mosby, Inc. All rights reserved.

In the patient with signs and symptoms of sinonasal inflammatory disease, CT, not MR imaging, is the suggested initial examination because the details of the bone/soft tissue/air interface are better seen on CT and the CT examination costs less than an MR imaging study. In addition, on MR imaging, because air, desiccated secretions, calcifications, and ossifications all give signal voids, they may be indistinguishable from one another. However, with CT, such differentiation is routine. Lastly, if there are no symptoms to suggest the intracranial spread of inflammatory disease, contrast is not necessary for the CT study. Thus, for most patients with sinonasal inflammatory disease, a noncontrast CT study provides the most detailed information at the lowest cost.

However, if the clinician suspects that a sinonasal tumor is present, the examination of choice is MR imaging due to its better differentiation of soft tissues. Thus, compared to CT, MR imaging can distinguish better between tumor and adjacent obstructed secretions or inflammatory disease.

To identify the early manifestations of sinonasal disease, it behooves the radiologist to become fluent in sinonasal anatomy as it appears on plain films, CT, and MR imaging. That is, before mastery in the analysis of pathologic cases is possible, the radiologist must be able to move confidently through the visual thicket of normal radiographic anatomy and its variants. The important role of the radiologist in evaluating disease in the sinonasal cavities is better appreciated when it is considered that the clinician can directly observe only a small portion of the volume of interest. Clearly, imaging provides the most thorough noninvasive evaluation of the nasal cavities and paranasal sinuses.

The following section addresses the normal sinonasal anatomy as seen on plain films, CT scans, and MR images. The common denominator leading to the successful interpretation of these examinations is the anatomy itself, and once this is learned, its depiction as rendered by any specific modality will be clearly and easily approached. Thus, technology per se is irrelevant as long as it meets the final test of delineation of structure. There are 22 bones in the facial area and calvarium that are routinely seen on images or films through the facial region: 1 frontal, 2 parietal, 1 occipital, 2 temporal, 1 sphenoid, 2 zygoma, 2 maxilla, 2 palatine, 1 ethmoid, 2 lacrimal, 2 nasal, 2 inferior turbinates, 1 vomer, and 1 mandible.

The normal sinonasal anatomy is presented in two sections. The first section discusses the normal anatomy as seen on plain films and contains a presentation of anatomic variants and potential problems that are created by overlying soft-tissue structures and bones.[32, 42–46] The second section presents sectional anatomy and is illustrated with CT images in the axial, coronal, and sagittal projections.[47–51] Further discussion of the paranasal sinus anatomy is presented in Chapter 3.

PLAIN FILM ANATOMY

The Frontal Sinuses

The main or vertical portion of the frontal sinuses is best visualized in the Caldwell and Waters projections (Figs. 2-10B and 2-11B). On occasion the Rhese view can better display some of the sinus contours, particularly in the smaller sinuses (Fig. 2-14B). The anterior and posterior sinus walls are best evaluated in the lateral and base (submentovertex) views (Figs. 2-9B and 2-17). However, in these projections, only those portions of the sinus walls that are parallel to the incident beam (perpendicular to the film plane) are visualized. The adjacent curvilinear surfaces are obliquely oriented to the incident x-ray beam and only contribute to the perceived density of the adjacent calvarium. Thus, on the lateral view, only the midsagittal anterior and posterior frontal sinus tables are visualized, and on the base view (depending on the angulation and the particular curvature of the skull), it is usually the caudal portions of the sinus walls that are identified. It is important to remember that only these limited areas of the frontal sinus anterior and posterior walls are seen routinely on these projections. One may not assume that the entire sinus table is normal simply because it appears intact on the lateral or base views. This is especially true in suspected fractures of the posterior table or if an erosion of this bone is in question. Sectional imaging clarifies this issue.

The horizontal portion of the frontal sinus is best seen in Caldwell (Fig. 2-18) and lateral (Fig. 2-9B) views. The depth of this recess can be best assessed by evaluating the posterior extent of pneumatization in the bony roof of the orbit, as shown on these projections.

Because the frontal sinuses develop independently from anterior ethmoid cells, asymmetry is the rule. Differential sinus growth is responsible for displacement of the intersinus septum to one side. However, this septum is usually near the midline at its caudal extreme, near the level of the glabella (Fig. 2-19). If the intersinus septum is displaced far to one side at this lower margin, an expansile process such as a mucocele within a frontal sinus should be suspected.

Unilateral or bilateral sinus aplasia or hypoplasia can occur. The smaller sinuses usually consist of a single, centrally concave recess (Fig. 2-20). Because of their small

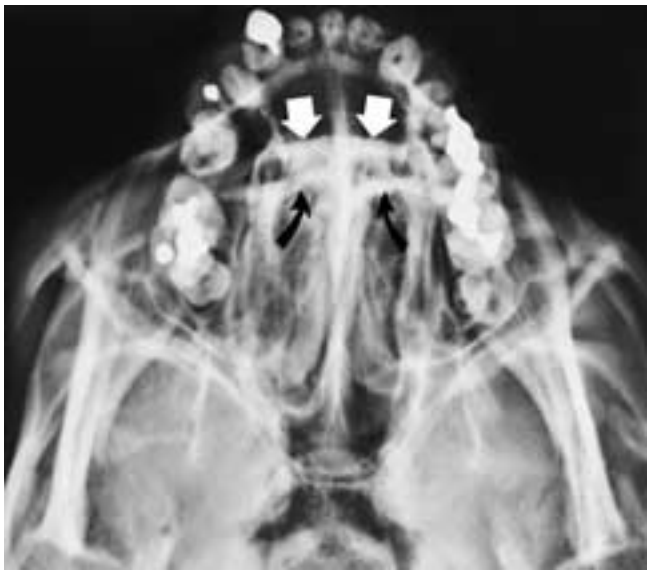

FIGURE 2-17 Overangulated base view with the anterior table of the frontal sinus (*large arrows*) and the posterior table (*curved arrows*) projected over the midpalate and nasal structures.

FIGURE 2-18 Caldwell view shows well-developed frontal sinuses. On the right side, the sinus pneumatizes the roof of the orbit. This is seen as air (*x*) contained within a thin white sinus margin (*arrow*) that is projected through the orbit.

FIGURE 2-19 Caldwell view shows a well-developed frontal sinus. Note the scalloped contour and the thin white mucoperiosteal line. Normal septations project into the sinus cavity (*white arrows*). The intersinus septum is to the right of the midline cranially but is near the midline caudally (*black arrows*). Despite the large size of the frontal sinuses, the orbital contours remain normal and are not encroached upon.

FIGURE 2-20 Caldwell view shows an aplastic right frontal sinus and a hypoplastic left frontal sinus. Note the smooth contour of the hypoplastic sinus.

size, there is little sinus air compared with the amount of overlying bone, and these sinuses almost always appear somewhat ''clouded'' on plain films, even if they are disease free. As such, they are difficult to evaluate. Rhese and Waters views may help to evaluate these small sinuses (Fig. 2-21).

The normally developed frontal sinus is always less dense than the adjacent frontal bone. The frontal bone, as part of the calvarium, is composed of cortical bone (forming both its inner and outer tables) and medullary bone (middle table, or diploic space) interposed between the two cortices.

FIGURE 2-21 Waters view shows hypoplastic frontal sinuses and a small central sinus cell, a not uncommon finding. This view complements the Caldwell projection for evaluating the frontal sinuses.

Copyright © 2003, Mosby, Inc. All rights reserved.

VIEW IMAGE

FIGURE 2-22 Caldwell view shows a moderately well-developed left frontal sinus. The right frontal sinus is aplastic. The perisutural sclerosis of the lambdoid suture is projected over the right frontal area and may mimic a clouded sinus contour. The ''linea nominata'' (*arrows*) is seen bilaterally. This line is formed by the greater wing of the sphenoid as it forms the calvarium in the anterior-most temporal fossa.

The diploic space is made up of a bony latticework that is less dense than cortical bone but osseous nonetheless. Frontal sinus development proceeds by invagination of an air-containing mucosal sac into the diploic space, thus replacing the osseous latticework of the medullary bone. Because the air-containing sinus cavity is less dense than medullary bone, the sinuses invariably appear less dense than the adjacent frontal bone. In general, the density of the normal frontal sinus is comparable to that of the superior orbital fissure as seen on the Caldwell view.

The larger sinuses normally have scalloped margins with septations that can project well into the sinus cavity (Figs. 2-18 and 2-19). If these scallops and septations are not seen and instead a smooth sinus contour is present, the diagnosis of a mucocele should be considered. The mucocele creates the smooth contour by progressively eroding the septations and remodeling the sinus shape.

Normally the frontal sinuses never violate the orbital contour, no matter how large they become (Fig. 2-19). If there is a downward and lateral flattening of the superomedial orbital rim, a mucocele should be suspected.

The normal superomedial orbital margin often appears unsharp on Caldwell and Waters views. This is because this area curves not only from medially to laterally in the orbital rim, but also from vertically to horizontally as the bone of the forehead region merges into the bone of the orbital roof. Usually a repeat Caldwell view at a slightly different angulation or a Rhese view allows this orbital margin to be visualized intact so that erosion is not erroneously diagnosed.

The margins of each frontal sinus are outlined by a thin (1 mm), dense rim, the mucoperiosteal (white) line, that separates the sinus from the adjacent frontal bone. If this line is not visualized, it could be the result of active infection, which is common, or bone destruction from tumor, which is rare. In the case of active inflammatory disease, there is increased mucosal vascularity that results in increased mobilization of the calcium in the surrounding bone, and this results in a loss of the mucoperiosteal white line. In chronic infection the thin, sharp white line is replaced by an unsharp, thick zone of sclerosis or reactive bone. This thickened white zone indicates only that the frontal sinus was exposed to previous chronic infection and does not necessarily imply that there is currently active sinus infection.

In the Caldwell view, the lambdoidal perisutural sclerosis of the occiput, a normal finding, can be projected over the region of the frontal sinus and can mimic a chronically thickened reactive margin of an opacified sinus (Fig. 2-22). Comparison of the Caldwell view to Waters or Rhese view permits correct interpretation.

On occasion, it is difficult to distinguish between a completely clouded (opacified) frontal sinus and an absent (aplastic) sinus. With good-quality films, some frontal sinus margin can almost always be identified, albeit poorly, on at least one of the plain films in the sinus series. If no such margin is seen, an aplastic sinus is the probable diagnosis. Sectional imaging will resolve any remaining issue.

On the lateral view a bone density area is usually seen at the base of the frontal sinuses anteriorly, near the nasion (Fig. 2-23). This represents the overlapping lower bony sinus walls and the superomedial orbital margins. The

FIGURE 2-23 Lateral view shows normal bone density near the anterior base of the frontal sinuses (*arrow*). This ''pseudo-osteoma'' is not seen on either the Caldwell or Waters view.

FIGURE 2-24 Caldwell view shows that the posterior ethmoid lamina papyracea (*small arrows*) is lateral to the more anterior lamina papyracea (*large arrows*). The medial orbital wall extends obliquely between them, reflecting the conical shape of the orbit. Also note the horizontally oriented normal ethmoid septa.

nasofrontal suture is usually situated just anteriorly. The dense bony area should not be confused with an osteoma. When seen from the front (Caldwell and Waters views), no osteoma is visualized and the bone in this region appears normal. Occasionally on the lateral view, small, bony ridges also are seen projecting from the anterior or posterior sinus walls. These are the sinus septa seen from the side.

The Ethmoid Sinuses

The ethmoid sinuses are best evaluated on the Caldwell view. However, in every plain film projection, some ethmoid cells are superimposed on others. This reflects the fact that the ethmoid sinuses are not a single sinus cavity, as are the other paranasal sinuses, but rather are formed by 3 to 18 cells that are packed into the ethmoid bone. This superimposition can lead to confusion on the plain film examination when the patient has symptoms referable to these cells, and yet the ethmoid sinuses appear normal. This situation arises because an isolated group of cells can be totally opacified, while all of the adjacent cells remain normally aerated. The air in these normal cells nullifies the plain film ''clouding'' of the infected cells, and the net result is often a very unimpressive plain film appearance. In this clinical circumstance, sectional imaging identifies any localized ethmoid disease.

On the Caldwell view, the normal density of the ethmoid sinuses can be judged by comparing it with the air density around the inferior turbinate of the nasal fossae. This reflects the fact that the ethmoid sinuses and the nasal fossae are of approximately the same anteroposterior depth, and thus the density of the air volume is about the same.

The thin lamina papyracea forms the lateral boundary of the ethmoid bone, separating it from the orbit. This medial orbital wall is oriented obliquely to an anteroposterior incident beam. Thus the majority of this oblique, thin, bony plate is not visualized on routine plain film studies. The straight or slightly concave lateral line that appears to form the medial orbital wall on a Caldwell view is in reality only the posterior ethmoid margin near the sphenoid bone. The anterior margin abutting the lacrimal bone is more medially placed and often is poorly seen (Fig. 2-24). It can be best localized by following the outline of the orbital rim from the superior aspect around to the superomedial margin and then caudally to the medial contour.

On the Waters view, only the most anterior ethmoid cells can be visualized, with the lacrimal bone separating them from the orbit (Fig. 2-25). The middle and posterior ethmoid cells are hidden from view by the nasal fossae structures. Similarly, the lateral and base views have so many overlapping structures that only gross localization of an ethmoid process can be achieved. On the base view the palate, nasal septum, turbinates, and anterior calvarium overlay the ethmoids, and on the lateral view the lateral orbital margins and even the frontal processes of the maxilla may project as vague dense zones overlying the ethmoid cells (Figs. 2-17 and 2-23). These should not be misinterpreted as sites of pathology. Although some isolation of the posterior ethmoid cells can be obtained on a Rhese view, some overlapping of ethmoid cells still occurs. Sectional imaging is indicated for proper mapping.

On the Caldwell view a small indentation, or groove, is often seen along the upper medial orbital wall. This is the anterior ethmoidal canal, and it transmits the vessels of the

FIGURE 2-25 Waters view isolates the anterior ethmoid cells and the overlying lacrimal bones (*arrows*).

VIEW IMAGE

same name along with the nasociliary nerve (Fig. 2-26). Because the canal is formed from the ethmoid bone below and the frontal bone above, it represents the level of the floor of the anterior cranial fossa. Less often seen on plain films are the posterior ethmoidal canals, which transmit the posterior ethmoidal nerve and vessels.

The ethmoidomaxillary plate is the posteroinferior boundary between the ethmoid and maxillary bones. It is best seen in the Caldwell view and is a useful plain film landmark for localizing the spread of tumors (Fig. 2-27).

Supraorbital ethmoid cells are ethmoid sinus extensions into the orbital plate of the frontal bone. Unlike the frontal sinuses, the supraorbital ethmoid cells tend to be symmetric. If such a cell is present on one side, it should be present on the opposite side. If one of these supraorbital cells is not seen, opacification or destruction should be suspected. Sectional imaging performed in the coronal plane resolves any questionable case. On the Caldwell view the supraorbital ethmoid cells appear as slightly curvilinear lucent zones in the superomedial orbital roof (Fig. 2-28). Their posterior extent is best evaluated on either a Waters or a lateral view. It is clinically important to ascertain whether a pathologic process is in a supraorbital ethmoid sinus or in the frontal sinus because the surgical approaches to these sinuses differ.

FIGURE 2-27 Caldwell view shows the ethmoidomaxillary plate (*curved arrow*). This is the boundary between the posteroinferior ethmoid bone and the maxillary bone.

VIEW IMAGE

The Maxillary Sinuses

The maxillary sinuses are best evaluated by the Waters view. Unlike the frontal and sphenoid sinuses, the maxillary sinuses tend to be symmetric in size and configuration, with only minor variations being common. When some degree of hypoplasia is present, the roof of the smaller antrum has a greater downward slant on its lateral margin than does the larger sinus (Fig. 2-29). On plain films this may simulate a blowout-type orbital floor fracture. However, in the hypoplastic sinus, there usually is an identifiably thicker lateral bony sinus wall that results from the poorer than normal pneumatization of the maxilla. Although this may be misdiagnosed as thickened sinus mucosa, this confusion is not likely to be made by the radiologist who is aware of the appearance of a hypoplastic antrum.

A small sinus can also result from diseases of the sinus wall that cause bone expansion, with resultant encroachment into the antral cavity. Such diseases include fibrous dysplasia, ''brown'' tumors of hyperparathyroidism, Paget's disease, and rare giant cell tumors. In these cases, at least one dimension of the original sinus may be identified as being fully developed, and the ''bony changes'' can be

FIGURE 2-26 Caldwell view demonstrates medial indentations in the lamina papyracea (*arrows*) that represent the anterior ethmoidal canals. These canals mark the level of the floor of the anterior cranial fossa.

VIEW IMAGE

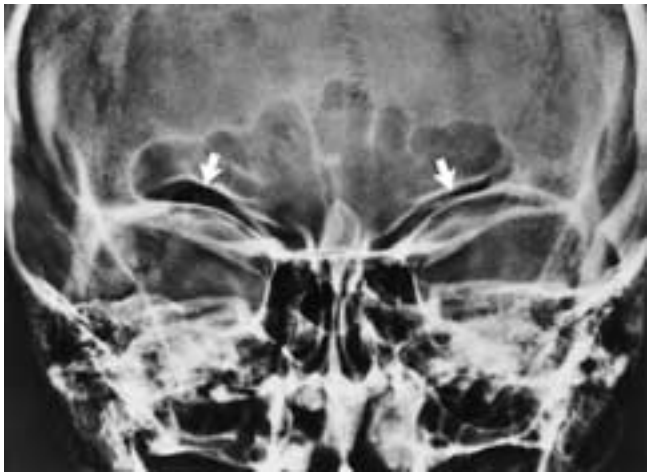

FIGURE 2-28 Caldwell view shows a curvilinear collection of air (*arrows*) just above each orbital margin. These areas appear darker than the frontal sinuses because the air in these supraorbital ethmoid cells is projected over the air in the frontal sinuses.

VIEW IMAGE

FIGURE 2-29 Waters view shows that the right maxillary sinus is smaller than the left. This hypoplasia is noted by the thicker lateral bony sinus wall and the more exaggerated downward slant of the sinus roof when compared with the left side. Also note that there is a suggestion of mucosal thickening in this normal hypoplastic right antrum due to its smaller sinus cavity and its thicker sinus walls when compared with the left side.

visualized bulging into the sinus, as well as being formed by abnormally textured bone. These changes differentiate these conditions from a simple hypoplastic antrum. Often sectional imaging may be necessary to resolve difficult cases.

Similarly, conditions that arrest the growth of the maxilla result in a small ''hypoplastic'' antrum. These childhood conditions include severe infection, trauma, tumor, irradiation, and congenital first arch syndromes.

The most lateral extension of the maxillary sinus is the zygomatic recess. This portion of the sinus hollows out the body of the zygoma, and when compared with the main antral cavity, it has less air and more surrounding bone. Because of this, the recess usually appears ''clouded'' on a Waters view and is often misinterpreted as representing mucosal thickening (Fig. 2-11B,C). True mucosal changes are best seen extending along the adjacent lower lateral antral wall.

On the lateral view, the anterior and posterior walls of the zygomatic recesses are seen as two overlapping V's projected over the main maxillary sinuses. These should be evaluated routinely to assess the possibility of early bone destruction in these recesses (Fig. 2-30). Also seen on the lateral view is the cranial continuation of the posterior wall of the zygomatic recess, the most anterior margin of the temporal fossa, which also represents the portion of the greater sphenoid wing that forms the oblique orbital line on the Waters and Caldwell views (Figs. 2-22 and 2-31).

The infratemporal maxillary sinus wall is a sigmoid-shaped, curved posterolateral surface. It is poorly seen on the Caldwell and Waters views. The most lateral extent (the back of the zygomatic recess) and the most medial margin (the anterior wall of the pterygopalatine fossa) can be identified on the lateral view (Fig. 2-31). The base view provides the best visualization of the curved nature of this wall, as well as an en face projection of portions of the pterygopalatine fossa and pterygoid plates (Figs. 2-32 and 2-33).

The medial wall of the maxillary sinus is best seen on the Caldwell view. Unfortunately, the overlying nasal structures anteriorly and the sphenoid sinuses and skull base structures posteriorly obscure most detail. Only the inferior turbinates and the lower medial antral wall are identified consistently. The clinically important osteomeatal complex is well visualized only on coronal sectional imaging.

Slight asymmetry, minimal rotation, and the physiologic nasal cycle all contribute to making one nasal turbinate larger than the other. As long as some air can still be visualized around the contour of the turbinate, separating it from the lateral nasal fossa wall and the nasal septum, the turbinate is probably not pathologically enlarged. Asymmetry per se should not be overdiagnosed as pathology. On the lateral view, the posterior tips of the inferior conchae are often seen projecting over the posterior antra, and they should not be confused with a pathologic mass (Fig. 2-34). Also on the lateral view, air trapped under or above the inferior turbinate can produce a linear lucency that may mimic a fracture.

Little consistent detail about the middle turbinates is obtained from plain film studies, and sectional imaging is necessary to provide accurate information.

FIGURE 2-30 Lateral view with large arrows pointing to the zygomatic recess of one maxillary sinus and small arrows outlining the opposite zygomatic recess. These recesses are routinely seen on lateral views as overlapping Vs. The air around them is air in the main maxillary sinus cavities, which are located nearer the midline. The S is in the sphenoid sinus, with its posterior and superior limits clearly visible on this lateral film.

VIEW IMAGE

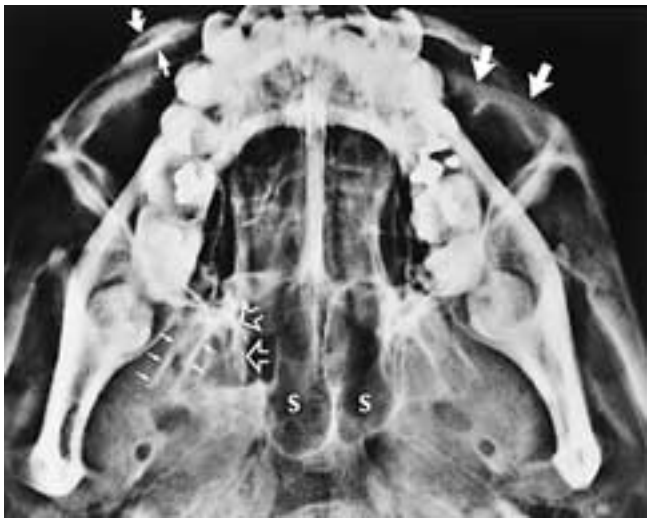
FIGURE 2-31 Lateral view with long arrows pointing to one posterior antral wall, which also forms the anterior margin of the pterygomaxillary fissure near the midline. The short arrow indicates the upward continuation of the posterior portion of one V that forms the zygomatic recess of one antrum (Fig. 2-30). The short arrow points to the bone just behind the orbit, which forms the anterior border of the temporal fossa. Open arrows indicate the upper, flat nasal fossa surface of the hard palate. The lower oral surface is slightly concave downward in configuration.

VIEW IMAGE

FIGURE 2-32 Base view with large arrows pointing to the curved anterior margin of the right middle cranial fossa (greater sphenoid wing). The small, straight arrows indicate the straighter posterior wall of the right orbit. The lateral margin is formed by the zygoma; the medial portion is formed by the greater sphenoid wing. The curved arrows outline the ''sigmoid-shaped'' posterior wall of the maxillary sinus. Each sphenoid sinus cavity (*S*) is seen well.



VIEW IMAGE

FIGURE 2-33 Base view with open arrows pointing to the medial pterygoid plate. Because the lateral pterygoid plate curves laterally as it descends from the skull base, the two small arrows point to the line of the lateral pterygoid plate near the skull base, and the three small arrows indicate the lateral pterygoid plate near the level of the hard palate. The large arrows point to the anterior wall of the left zygoma and maxilla. The frontal bone's anterior table (*curved arrow*) and posterior table (*small, straight arrow*) are also indicated on the right side. Each sphenoid sinus cavity (*S*) is seen well.

The anterior antral wall is not well seen on any view. Both the lateral and overangulated base views reveal only limited portions of this wall (Fig. 2-33).

The lateral view best delineates the inferior extension of the maxillary sinus and its relationship to the hard palate and teeth roots (Fig. 2-35). The sinus cortex of this alveolar recess can be elevated normally by unerupted molar teeth. Although this is well seen on the lateral view, its often broad upper surface can simulate an air-fluid level or a localized mass on a Waters view. This is especially notable in older children and teenagers.

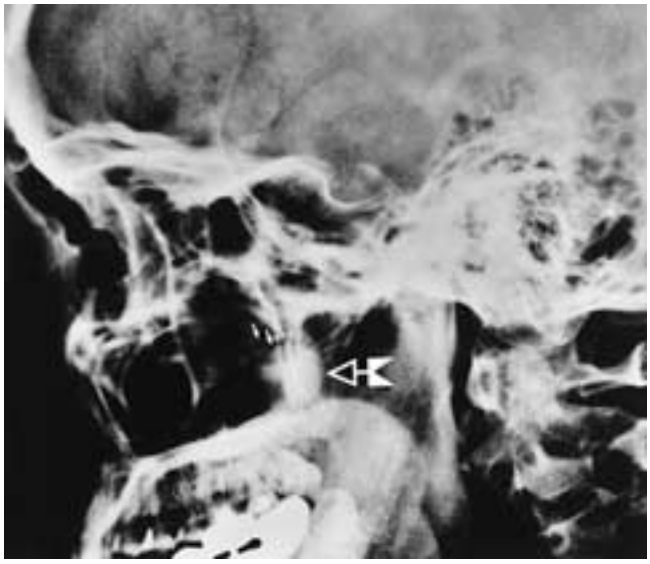


FIGURE 2-34 Lateral view with the large arrow pointing to the posterior tip of the normal inferior turbinate. Normal air just above the turbinates (*small arrows*) may mimic a fracture line.

VIEW IMAGE

FIGURE 2-35 Lateral view demonstrates maxillary sinus extension (*black arrowheads*) below the level of the hard palate (*white arrowhead*). The shorter arrows point to the anterolateral and most inferior orbital floor on one side, and the longer arrows point to the posteromedial and most superior orbital floor near the orbital apex.

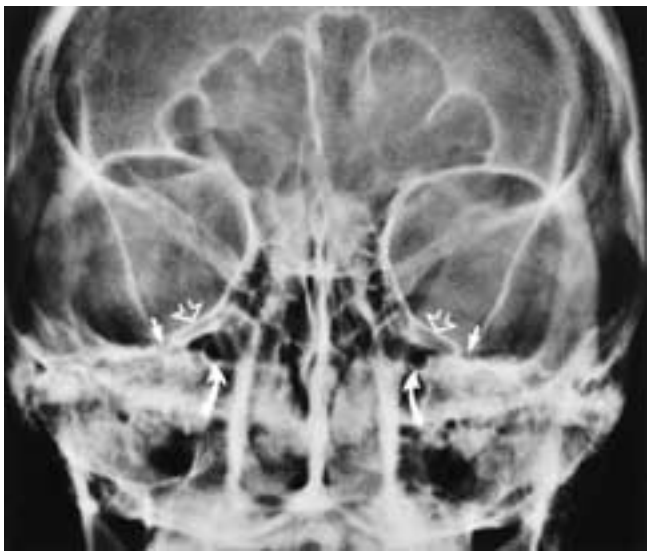
The antral roof, or orbital floor, is flattest and lowest anterolaterally. It is also highest and most angulated posteromedially. The majority of the midportion of the antral roof is seen almost tangentially on a Caldwell view, and thus this large surface is usually seen as a single line in this projection. On the Caldwell view a second, smaller, more slanted line is seen superomedially in the orbital floor. This line represents the orbital apex floor; a notch at the lateral aspect of this line identifies the site of the infraorbital groove (Fig. 2-36).

On the lateral view the orbital floor is usually seen as two separate lines; one anteriorly, near the level of the inferior orbital rim, represents the lowest, most lateral, and flattest area of the floor; the second, located higher and more posteriorly, represents the medial orbital apex region. The slanting floor joining these two areas is not normally seen on the lateral view (Fig. 2-35). However, on a nonconed Rhese view (or optic canal view), the contralateral orbital floor is often seen extending from the anterior orbital rim almost to the orbital apex.

The Waters projection gives a better view of the inferior orbital rim. However, much of the orbital floor is seen obliquely en face, and small fractures, depressions, or erosions may not be detected. Three roughly parallel lines are seen near the inferior orbital margin in the Waters view. The most superior of these is the soft-tissue skin margin overlying the inferior orbital rim. The middle line is the actual bony inferior orbital rim, and the lowest line is the roof of the antrum located about 1 cm behind the rim, the lowest point of the orbital floor. About 1 cm below the middle third of the inferior orbital rim, the infraorbital foramen is seen. It transmits the second division of the trigeminal nerve to the cheek and nasal region (Fig. 2-37).

On the Waters view a small lucency is occasionally seen in the lateral antral wall. This is the canal for the posterior superior alveolar nerve and should not be confused with a fracture (Fig. 2-38).

On the Caldwell view the foramen rotundum is projected through the superomedial portion of the antrum (Fig. 2-36).



VIEW IMAGE

VIEW IMAGE

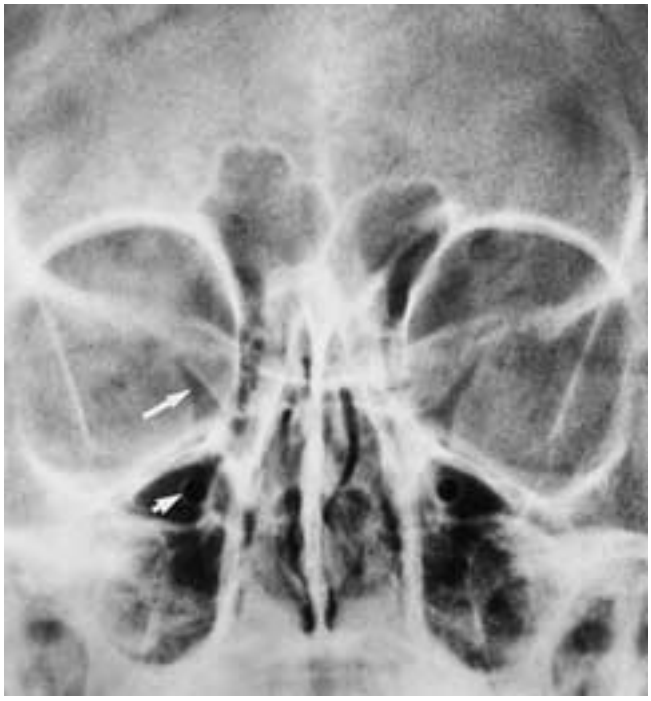
FIGURE 2-38 Waters view with arrows indicating the canals for the posterior and superior alveolar nerves.

The superior orbital fissure is easily identified and normally has a slightly concave lateral appearance (Fig. 2-39). If the superior orbital fissure is followed inferiorly and slightly laterally, it points to the foramen rotundum. The maxillary nerve (V_2) runs through this foramen, crosses the pterygopalatine fossa and retromaxillary fissure, enters the infraorbital fissure, exits via the infraorbital canal, and supplies the cheek and nasal regions.



VIEW IMAGE

FIGURE 2-39 Caldwell view shows the superior orbital fissure (*large arrow*) and the foramen rotundum (*short arrow*), which is at the lower lateral margin of the superior orbital fissure.

The two foramina rotunda are usually symmetric in size and configuration. The superior orbital fissures, on the other hand, need not be as symmetric. The most important observation is that the bony cortical rims on either side of each fissure are thin and sharply defined. These fissures are narrower superolaterally and wider inferomedially. It is through this wider area that the veins and nerves traverse the fissure (Fig. 2-39). On the Waters view the lower portions of the superior orbital fissures are projected through the upper medial antra. These can simulate either a fracture of the inferior orbital rim or a septum of the antral roof (Fig. 2-37).

The infraorbital fissure can sometimes be seen on the Waters view as a pair of parallel thin cortical lines that are oriented anteroposteriorly. Their course is parallel, rather than divergent, and their configuration distinguishes them from the posteriorly located superior orbital fissure.

The inferior orbital fissure is poorly seen on the routine sinus views and can be best evaluated on the Towne view (Fig. 2-40).

The oblique orbital lines (linea innominata) are seen in both the Waters and Caldwell views. They represent the most anterior portions of the medial temporal fossa and usually are formed by the greater sphenoid wings. At the lower margin of each innominate line a sharp medial turn is seen, indicating the lower margin of the temporal fossa and the beginning of the infratemporal fossa. Occasionally

FIGURE 2-40 Towne view with arrows outlining the margins of the inferior orbital fissure. The superior line is formed by the sphenoid bone, and the inferior line is formed by the maxilla.

VIEW IMAGE

FIGURE 2-41 Waters view with arrows pointing to the left oblique orbital line. At its lower margin the line bends medially at the level of the infratemporal fossa. The line then bends downward at the level of the lateral pterygoid plate. The small white arrows point to the upper rim of the right middle cranial fossa. The open arrows indicate the left nasal margin, which can mimic a cyst or polyp in the medial antrum.

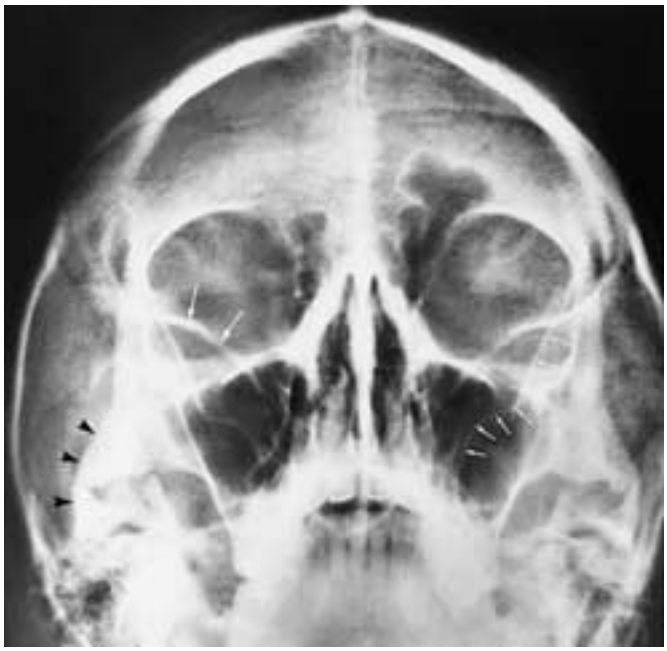

FIGURE 2-42 Waters view with smaller arrows outlining the left oblique orbital line, its inferior extension to the infratemporal fossa, and finally the lateral pterygoid plate. The larger arrows point to the upper anterior margin of the right middle cranial fossa. The arrowheads outline the right zygomatic arch.

VIEW IMAGE

this line is seen to continue medially and then bend downward, outlining the lateral pterygoid plate (Figs. 2-41 and 2-42).

The superior bony margin of the middle cranial fossa is a concave posterior ridge that is formed medially by the lesser sphenoid wing and laterally by the posterior edge of the orbital plate of the frontal bone. The curved margin can be seen projected through the orbit and upper antrum on the Waters view (Figs. 2-41 and 2-42).

The body of the zygoma and the zygomatic arches are well seen in the Waters and base views (Figs. 2-17 and 2-42). Alternate views for this arch are the underpenetrated base view and the ''jug handle,'' or oblique zygomatic projection. The posterior portions of the arch are best seen on a Towne view. The zygomaticotemporal suture in the zygomatic arch is an obliquely oriented line that is seen routinely and should not be confused with a fracture. Occasionally the zygomaticofacial canal can be seen in the lateral body of the zygoma. It transmits the zygomaticofacial nerve.

On the Waters view the soft-tissue shadow of the upper lip is often seen traversing the lower antrum (Fig. 2-43). This shadow usually extends laterally to the lower maxillary sinus margin. Similarly, a mustache also can produce such a shadow. These soft-tissue densities should not be confused with true retention cysts of the lower antrum, which unlike the shadows just described can be identified as cysts on a lateral view. Similarly, the nasal alae can mimic cysts of the medial antral wall in the Waters view (Fig. 2-41).

Soft-tissue swelling of the cheek can mimic ''clouding'' of the antrum on a Waters view. This usually can be identified by elevation of the superior skin line over the inferior orbital rim. However, sectional imaging may be necessary in some cases to isolate the maxillary sinus from the overlying swollen skin and subcutaneous tissues.

In the lateral view the coronoid processes of the mandible project over the inferoposterior maxillary sinuses. This is

FIGURE 2-43 Waters view with arrows outlining the shadow of the upper lip, which is projected over the lower maxillary sinus.

VIEW IMAGE

Copyright © 2003, Mosby, Inc. All rights reserved.

especially noted if the mouth is closed. If these coronoid processes are blunt or rounded, they may simulate retention cysts (Fig. 2-44). If the coronoid processes are sharply pointed, they may simulate a fractured bone segment or an unerupted tooth.

The Sphenoid Sinuses

The sphenoid sinuses are probably the most difficult sinuses to evaluate by routine films because they are buried deep in the skull base and are surrounded by the facial bones, nasal cavity structures, and occiput on the frontal views; the mastoids and lateral skull base structures on the lateral view; and the calvarium and pharynx on the base views. The sphenoid sinuses are extremely variable in their configuration. About one half of the population has only a central sinus cavity, and the other half has, in addition, lateral recesses. These recesses can extend into the greater wings of the sphenoid, lesser wings, and pterygoid processes.

The central, or main, sphenoid sinus cavity is best evaluated on the lateral, base, and open-mouth Waters views (Figs. 2-30 and 2-33). The sinus roof (planum sphenoidale), the sella floor (lamina dura), and the posterior development of the sinus cavity are all well seen on the lateral view; the floor and anterior sinus walls, however, are partially obscured by the overlapping lateral skull base. The base view provides a means of evaluating the sinus depth and lateral extension. The open-mouth Waters view allows evaluation of the lower posterior sinus wall as it is projected through the mouth.

VIEW IMAGE

FIGURE 2-44 Lateral view with arrows pointing to the coronoid process of the mandible, which is projected over the lower posterior antrum in this closed-mouth view.

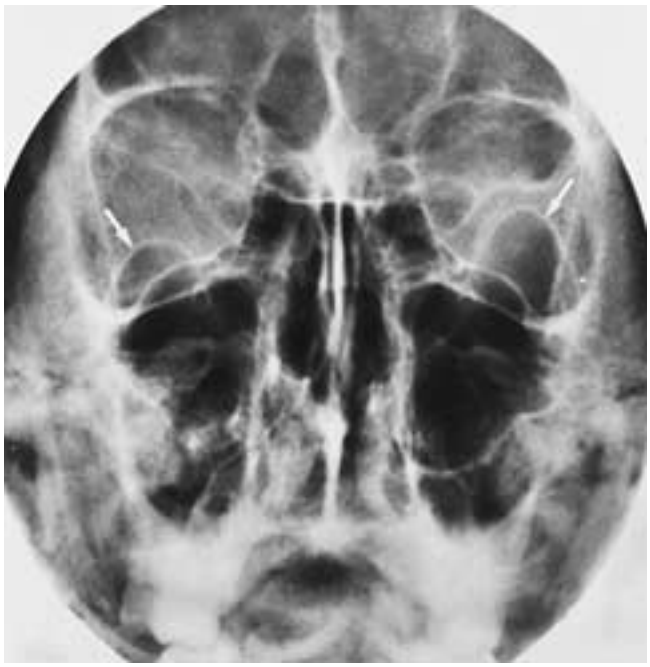

FIGURE 2-45 Caldwell view shows lateral sphenoid sinus pneumatization of the greater sphenoid wings as they form the posterior orbital walls (*arrows*). They are limited on all but their inferomedial margins (where they join the main sinus cavity) by the thin white mucoperiosteal line of the sinus margin.

VIEW IMAGE

The lateral sinus extensions into the greater wing of the sphenoid can go into the floor of the middle cranial fossa and up into the posterior orbital wall. These extensions are seen best on the Caldwell and Waters views. On the Caldwell view the ''orbital recess'' is seen as a ''lytic'' area in the lower lateral orbit. There is a thin cortical white line outlining its contour except in its lower, medial portion. It is at this margin that this sphenoid recess communicates with the main sinus cavity (Fig. 2-45). On the Waters view the lateral sphenoid sinus recesses in the floor of the middle cranial fossae are projected through the maxillary sinuses. They have a variable shape, depending on the configuration of the recess. They can appear as ''dog ears'' or can simulate compartments of the maxillary sinus (Fig. 2-46). Regardless of their shape, they always join the central sphenoid sinus medially and, when normal, are always rimmed by a thin white cortical line.

Pterygoid pneumatization results in a triangular lucency in the pterygoid plates in the lateral view and a round or oval lucency in the pterygoid process in the base view (Fig. 2-47). These recesses, when normal, are again outlined by a thin white cortical line.

The plain film appearances of all of these recesses are classic. Once they are mastered, the interpreter should not confuse them with pathologic processes.

In patients with a pituitary mass who may require a transsphenoidal surgical approach, special attention should be given to evaluating the posterior extent of the main sphenoid sinus cavity. If more than 1 or 2 mm of bone remains between the posterior margin of the pneumatized sinus and the anterior sella wall (less than 1% of the cases), most surgeons avoid a transsphenoidal hypophysectomy. This relationship is most easily seen in the lateral view.

VIEW IMAGE

FIGURE 2-46 Waters view shows lateral recesses of sphenoid sinuses extending into the greater sphenoid wings in the floor of the middle cranial fossa. The arrows outline the right ''dog-ear-shaped'' recess projected through the maxillary sinus. There is also a recess on the left side.

Associated Structures Surrounding the Paranasal Sinuses

There are a number of important structures that surround the paranasal sinuses and project over them on the plain film examinations.

On the lateral view, the anterior walls of the middle cranial fossa are seen as paired curvilinear lines that project over the sphenoid sinus cavities and merge posteroinferiorly with the bone density of the skull base. The planum sphenoidale is clearly identified as a straight, bony line. The cribriform plate is not as well seen as it continues anteriorly from the planum sphenoidale. However, a line drawn connecting the nasion and the anterior planum very closely approximates the level of the cribriform plate. The fovea ethmoidalis (ethmoid sinus roofs) lie just lateral to and above the cribriform plates. They usually are identified as slightly concave, downward thin, bony lines positioned just above the plane of the cribriform plates. The orbital roofs are situated higher and more laterally than the fovea ethmoidalis. Thus one can roughly localize a lytic process on a lateral film by evaluating which of these lines is eroded. The more superior the line, the more lateral the process (Fig. 2-48). The midline crista galli is best seen on the Caldwell view. This intracranial structure rests on the midline upper surface of cribriform plates.

The bony nasal septum is not seen optimally on any plain film projection, but it is best evaluated on the Caldwell view. Only gross deviation of the bony septum can be appreciated. The cartilaginous septum is poorly seen on plain films and is well visualized only on sectional imaging.

In the lateral view the anterior nasal spine usually has a sharply triangular appearance. The film must often be ''bright lighted'' to properly evaluate the spine. Destruction of the anterior nasal spine should raise the question of prior surgery or trauma. Midfacial anomalies, Hansen's disease (leprosy), other infectious processes, and carcinomas can also result in nonvisualization of this spine.

The hard palate is best evaluated in the lateral view. Its upper nasal surface is flat and usually has a clear cortical margin. The lower oral surface is slightly concave downward, and it also has a good cortical margin (Fig. 2-31).

In the base view, three paired lines are consistently seen. The most posterior of these is concave posteriorly and represents the greater wings of the sphenoid bone as they form the anterior margin of the middle cranial fossae. The second and most often the anterior pair of lines are relatively straight, being obliquely oriented to the midsagittal plane and open-faced anteriorly. Each line is composed medially by the sphenoid bone as it forms the posterior orbital wall and laterally by the orbital surface of the zygoma. The suture between these bones often can be identified clearly. Medially these two sets of paired lines (each primarily formed by the sphenoid bone) join at the pterygoid processes. The third pair of lines are sigmoid (S-shaped) and represent the infratemporal or posterolateral antral walls. Depending on the angulation used to make the base view, the sigmoid line can be anterior to, overlapping and crossing, or posterior to the orbital lines (Figs. 2-32 and 2-33).

In the base view the pterygoid fossa is seen as a V-shaped space with its apex placed anteriorly. The pterygoid plates are usually seen as three thin, bony lines. The medial pterygoid plate is seen as a single line. However, the lateral pterygoid plate is seen as two separate lines, a lateral line that represents the most caudal end of the lateral pterygoid plate at the level of the hard palate and a central or medial

FIGURE 2-47 Base view with large white arrows outlining the pneumatized pterygoid process. The small black arrows point to the foramen spinosum, and the large black arrow indicates the right foramen ovale. The small white arrows outline the posterior margin of the tongue.

VIEW IMAGE

FIGURE 2-48 Lateral view with small arrows pointing upward indicating the planum sphenoidale in the midline. The small arrows pointing downward outline the roof of the ethmoid sinuses (fovea ethmoidalis). The long arrows indicate the laterally positioned roofs of the orbit. The short arrows outline the curved anterior margins of the middle cranial fossa.

line that represents the lateral pterygoid plate near the skull base. The lateral pterygoid plate is seen as two lines because this plate has a curved, laterally tilted shape, which results in the main body of this plate being oblique to a craniocaudal incident beam. As a result, only the upper and lower bony margins are directly ''on end'' to the beam. Occasionally the hamulus of the medial pterygoid plate can be seen on the base view. The pterygoid fossa is thus the space, open posteriorly, between the medial and central pterygoid lines near the skull base and between the medial and lateral lines near the hard palate.

In the base view the frontal bone casts two transverse lines across the anterior portion of the ethmoid and maxillary sinuses. These lines correspond to the anterior and posterior cortices of the frontal bone. In addition, the anterior surface of the body of the zygoma and the anterior wall of the maxilla cast a transverse line across the anterolateral skull base. The relationship of the frontal table lines to the zygomaticomaxillary lines depends on the particular angulation used in the base view (Figs. 2-32, 2-33, and 2-49). In the more markedly angulated base view, the lacrimal canals can also be seen projected through the medial antral walls and hard palate.

The nasopharyngeal soft tissues should be carefully and routinely examined because disease can spread from this area into the sinonasal cavities and vice versa. This evaluation is best accomplished on the lateral view. The presence of a soft-tissue fullness in the roof and uppermost posterior wall of the nasopharynx may indicate adenoidal tissue, lymphoma, nasopharyngeal carcinoma, a Thornwalt cyst, or other lesions. If an ''adenoidal'' mass abuts on the upper surface of the soft palate, it may account for respiratory-related symptoms such as snoring or sleep apnea. Thus obliteration of the posterior nasal airway should always be noted in the radiologist's report.

On the base view the uvula, the posterior surface of the soft palate, and the back of the tongue all can cast transverse soft-tissue shadows across the skull base. In particular, the tongue base is often visualized extending transversely across the sphenoid sinuses. This should not be confused with sinus ''clouding'' and should be correlated with the lateral and open-mouth Waters views. The air in the nasopharynx and oropharynx is routinely seen as a low-density region projected over the central skull base. The degree of tube angulation and neck extension determines if this air shadow primarily represents the nasopharynx or the oropharynx. Thus a rectangular shadow with its greatest dimension extending from side to side suggests the nasopharynx, while a more square-shaped shadow suggests the oropharynx. On the routine base view, fullness in the region of the palatine tonsils can produce lateral soft-tissue

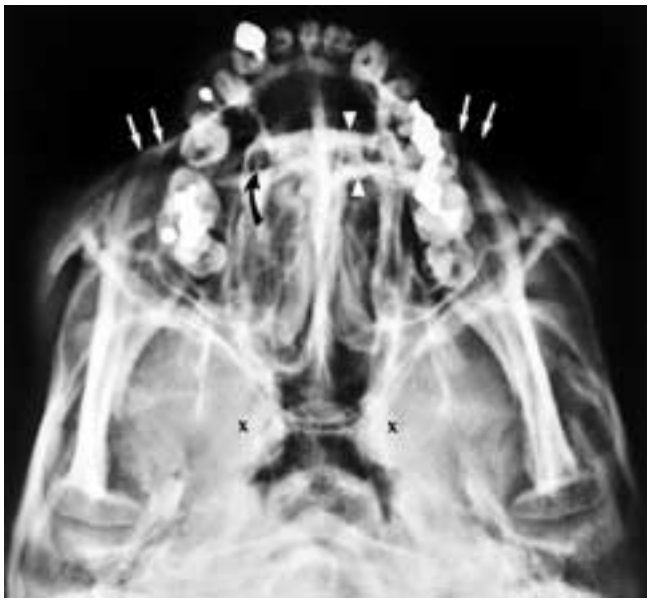

FIGURE 2-49 Base view with arrows indicating the anterior wall margin of the maxilla and the zygoma. The curved arrow points to the nasolacrimal duct, which in this film is projected over the frontal bone's anterior and posterior margins (*arrowheads*). The soft-tissue shadows of the palatine tonsils (*Xs*) can also be seen.

masses that overlie the posterior nasal fossae and pharyngeal airway (Fig. 2-49).

On the lateral view the pinna of the ear occasionally is projected over the sphenoid sinus and nasopharynx. This may simulate a mass and is usually seen on slightly underpenetrated films. It can be identified as an artifact by tracing out the entire ear lobe.

The nasal bones are best evaluated in the lateral view (Fig. 2-15B). The nasofrontal suture is identified easily at the level of the nasion. Also, the nasomaxillary sutures can often be seen. There are no normal sutures or bone segments that routinely traverse the midline nasal bones. However, several radiolucent lines are usually present in the lateral aspect of the nasal bones. These lines, which are the normal grooves for the nasociliary nerves and vessels, roughly parallel the plane of the midline nasal bones, and they should not be confused with fractures. As a general rule, there should be no lucent lines that extend across the midline nasal bones, and any such line or lines must suggest the diagnosis of a fracture. Medial depression of the nasal bones is best evaluated in the occlusal (axial) and Waters views. As mentioned, when evaluating the nasal bones, attention should also be paid to the anterior nasal spine.

In a patient with recent nasal trauma, clinical examination can usually determine whether a fracture is present. The examiner places the thumb and index finger on either side of the bridge of the nose and gently rocks the fingers from side to side. In cases of fracture the patient has exquisite local pain. By comparison, if there is only hemorrhage and edema (often markedly deforming the nasal contour) without fracture, the patient is only slightly tender. Thus, in such cases, strictly speaking the x-ray request for nasal films should read ''Nasal fracture, please evaluate for the number of fractures and any displacement'' rather than ''Rule out a nasal fracture.'' The radiologist's report should include a comment on the number and location of the fractures and whether there is depression or elevation of the fracture segments. These nasal fractures are usually best seen on sectional imaging.

SECTIONAL IMAGING TECHNIQUES

Computed Tomography

The mucosal surfaces and the bony framework of the sinonasal cavities are well suited for investigation by CT. Because the radiologist and the clinician are as interested in soft-tissue disease as they are in bony changes, it would be convenient if each scan could be viewed at an appropriate window and center level that optimizes both subtle soft-tissue differences in attenuation as well as fine bony detail. Unfortunately, there is no one combination of window and center (level) settings that optimally accomplishes both of these aims. The soft tissues are best shown at narrow windows that allow easy discrimination between the attenuation values of muscle, fat, and tumor, as well as some distinction between entrapped secretions and cellular soft tissues. In addition, narrow windows allow prompt detection of any enhancement differences on contrast-enhanced CT scans. Such soft tissue settings have window values in the range of 150 to 400 HU.

Conversely, bone detail is best shown at wide window settings in the range of 3000 to 4000 HU. In addition, these wide window settings allow the most accurate evaluation of the air soft-tissue interfaces. This reflects the fact that almost all commercial vendor algorithms have difficulty handling abrupt transitions in attenuation values from very low (air) to very high (bone) attenuation regions. Thus, when the same images are viewed side by side at both narrow and wide window settings, the air spaces and the bones always appear larger at the narrower settings but are more accurately seen at the wider window settings (Fig. 2-50).

The appearance at wide window settings correlates accurately with the true measurements of the air spaces and the thickness of both soft-tissue disease and bone. In addition, at narrow window settings, volume-averaging errors allow a small soft-tissue mass to be obscured by surrounding sinus air and a focal area of abnormal bone to be obscured by adjacent normal bone.

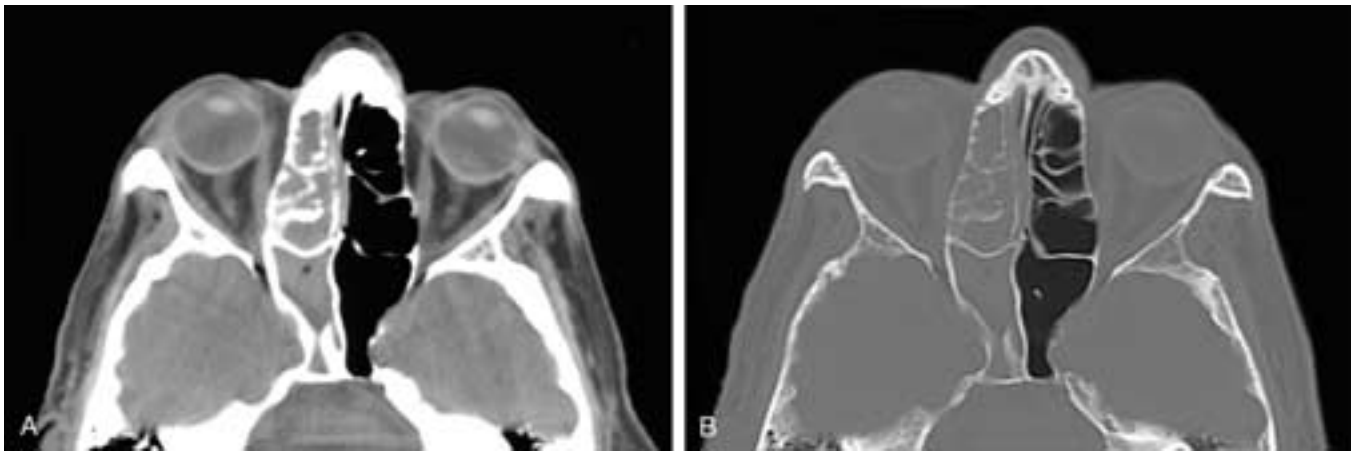

FIGURE 2-50 **A**, Axial CT scan through the ethmoid and sphenoid sinuses viewed at narrow ''soft-tissue'' window settings shows opacification of these sinuses, with apparent sclerosis and thickening of the surrounding bone and ethmoid septae. **B**, Same image viewed at wide ''bone'' window settings shows that the bones are not sclerotic and thickened. The wide window views of the bone most closely reflect the actual bony changes.

VIEW IMAGE

In summary, the most accurate assessment of mucosal soft-tissue disease and bone is accomplished at wide window settings. However, the best distinction of watery sinonasal secretions from more viscous or desiccated secretions or a tumor requires narrow window settings.

Because of the popularity of endoscopic sinus surgery and its focus on the osteomeatal complex, the limited coronal CT study has become the most requested imaging examination of the sinonasal cavities. These studies best show the osteomeatal unit and are designed to limit the patient's radiation dose. Such limited CT examinations also are comparable in price to a plain film study. Although this approach is adequate for most patients, there are some pitfalls in interpreting such limited studies. Specifically, the anterior and posterior walls of the frontal, maxillary, and sphenoid sinuses are not well seen in the coronal view, and any abnormality or violation of these walls is most often overlooked or underestimated if only coronal views are available. In addition, because of varying patient compliance with the degree of neck extension, the coronal scan angle varies from patient to patient and often from examination to examination on the same patient. This alters the appearance of some anatomic landmarks and may make precise localization of ethmoid disease difficult. Such variation may soon be eliminated with the greater use of the multidetector CT scanners that allow precise coronal plane reconstructions from axial scans.

The axial studies provide the best CT evaluation of the anterior and posterior sinus walls. Thus, while a limited coronal CT study may be an adequate examination for most patients with suspected inflammatory sinonasal disease, the interpretation of such a study must be viewed with a caveat in mind. Namely, whenever there is total opacification of the frontal, maxillary, or sphenoid sinuses, a complete axial and coronal CT examination should be performed. In addition, if the patient has a suspected neoplasm, a complete axial and coronal examination ought to be performed to provide the most detailed analysis of the sinonasal cavities and the adjacent skull base.[52–54]

The axial examination is most often performed with the patient supine, the hard palate perpendicular to the table top, and the scanning plane parallel to the inferior orbitomeatal (IOM) line. The IOM line is readily identified on a lateral scout view. In addition, the cranial and caudal limits of the average scan (a level just above the top of the frontal sinuses and the bottom of the maxillary teeth, respectively) can be easily localized off the lateral scout view. The routine study should be obtained as 3 mm contiguous scans throughout the scan volume. Narrower slice thicknesses are usually unnecessary unless there is a specific region of interest. Spiral CT can also be performed at 3 mm intervals and reconstructed at 1 to 3 mm intervals.

Just as volume averaging may cause diagnostic difficulties in the coronal view, there are three levels in the axial view that may cause interpretive difficulties. These levels correspond to three bony planes, all of which are nearly parallel to the axial scan plane: the floor of the anterior cranial fossa, portions of the orbital floor, and the hard palate. Because knowledge of extension of disease across these bony planes is critical for the surgeon in determining some surgical procedures (for example, an antral tumor growing into the orbit, or a nasoethmoid or sphenoid tumor extending into the anterior cranial fossa), a coronal study must also be obtained whenever imaging of these bony planes is essential.

Because most adult patients have dental amalgams or metal bridges that cause considerable artifact, direct 90° coronal CT scans (to the IOM plane) are usually of limited diagnostic value because the involved teeth lie immediately below the sinonasal areas of interest. In addition, many patients cannot sufficiently extend their necks (because of pain, vertigo, arthritis, etc.) in either the supine or prone position to obtain such 90° coronal studies. In general, a scan plane is chosen that extends from a caudad margin just anterior to the dental fillings to a cranial point just posterior to the area of greatest interest (osteomeatal unit, orbit, sphenoid, etc.). These coronal studies are routinely obtained as 3-mm-thick contiguous slices.[55, 56] Spiral CT is now a viable alternative technique to the conventional multislice approach. This may be especially pertinent in the coronal view, where the faster spiral CT minimizes patient motion. In addition, the newer multidetector CT scanners allow excellent coronal images to be created at any desired scan angle from images made in the axial plane.

The routine CT study performed to evaluate sinonasal inflammatory disease does not require intravenous contrast administration. However, if one needs to determine if a nasal mass extends into an adjacent sinus or simply obstructs the sinus, or if there is suspected intracranial extension of disease, contrast should be given. In such instances, contrast CT is usually performed because the patient cannot have an MR study, as MR better visualizes mass/secretion interfaces and intracranial disease. There are a variety of methods for administering the CT contrast, and today a power injector is commonly used. If multiple serial CT slices are obtained, a small volume (10 to 20 ml) may be given as a bolus to ''load'' the patient and then the remaining contrast given at a slower rate throughout the examination. If spiral CT is used, the rapid scanning time allows the delivery of a larger effective bolus throughout the examination.

Magnetic Resonance Imaging

As the era of MR imaging proceeds, new sequences and techniques are constantly being suggested. However, these approaches are primarily variations of facilitating the acquisition of basic T1-weighted and T2-weighted information. The advantage of imaging without ionizing radiation is occasionally outweighed by a claustrophobic patient's rejection of the procedure (about 10% of cases) or the presence of metal hardware, foreign bodies, or a pacemaker that abrogates the examination. Industry has responded to most of these problems by producing implantable nonmagnetic materials, nonparamagnetic support equipment for use with the more critically ill patient, and open MR units. Although bone is not directly imaged on MR, invasion of bone marrow and gross bone erosion can be easily identified.[57, 58] Fine bone alterations as well as focal calcifications are difficult, if not impossible, to see on MR imaging, and they are far better demonstrated on CT.

There stills remains some debate regarding the indications for the use of MR contrast material. Below the skull base, contrast enhancement occurs in most tumors and

Copyright © 2003, Mosby, Inc. All rights reserved.

inflammatory tissue, as well as in some normal mucosa. As a result, the region of enhancement may contain a variety of normal as well as pathologic tissues, and the actual pathology may appear larger than it actually is. Despite this, some authors have recommended the use of double- and even triple-dose MR contrast agents to better assess the pathology visually. However, no new pathology was identified in such high-dose studies, and today single contrast dosing is the rule.[59] Actually, in day-to-day practice, pathology is often better mapped on noncontrast T1-weighted and T2-weighted images than on enhanced studies. However, if the pathology has spread intracranially, contrast-enhanced MR is superior to noncontrast studies in demonstrating an intracranial tumor margin and dural disease, as well as any intracranial complications of sinusitis such as meningitis, cerebritis, intracranial abscess, and orbital complications.[59, 60] Some radiologists firmly believe that fat suppression offers better visualization of contrast-enhanced areas. This is especially true when there is orbital involvement. However, other radiologists believe that the use of fat suppression techniques introduces unwanted artifacts that complicate image interpretation. Although most studies are done with fat suppression, the final decision is based on the preference of the radiologist.

MR contrast may also help in differentiating between entrapped secretions and a solid mass, as there is peripheral enhancement of uniformly thick, inflamed mucosa around secretions, while there usually is enhancement of a tumor nodule either centrally or along the margin of a neoplasm.[61, 62] Lastly, an MR contrast-focused study of the skull base and cavernous sinuses is the best way to identify perineural tumor spread. This topic is discussed in detail in Chapter 13.

The basic MR examination usually includes axial and coronal images. The scan thickness should be 3 to 5 mm, and a narrow interslice distance (1 mm) is suggested. Basic or equivalent T1-weighted and T2-weighted information should be obtained, whether by conventional spin echo or fast scan imaging. Fat suppression can be used in selected cases but is rarely necessary unless contrast-enhanced sequences are also obtained. The best study for an individual patient is often the one that is most confidently read by the radiologist. Thus sagittal images, though not necessary in the routine case, may help, especially in evaluating the cribriform plate region or the orbital floor. Gradient echo or FLAIR-type images can also be obtained to confirm the presence of hemorrhage.

Because there is no uniformity in the literature regarding the optimal TR and TE, these parameters can be varied to some degree to limit the total duration of the MR study, alter the resolution, or produce more scan slices in a single scan sequence. The greatest challenge for the imager is to tailor the examination to each patient so that all of the necessary information is gathered without unduly lengthening the examination. An additional benefit of this approach is that more patients can be examined in a given work day.

SECTIONAL IMAGING ANATOMY

This section highlights the anatomy that can be seen on CT and MR imaging of the sinonasal cavities. The anatomy is divided into sections to help organize the anatomic detail. For specific anatomic descriptions of the sinuses, one should also review the previous sections dealing with plain film anatomy. Only the pertinent anatomic details are mentioned in the following sections. The reader is also referred to the images in the atlas section.

The Nasal/Palatal Region

Far anteriorly on coronal images, the nasal bones and frontal processes of the maxilla form the upper outer nasal contour.[47] The upper nasal septum is formed by the perpendicular plate of the ethmoid bone above and the septal cartilage below. Inferiorly, the premaxilla is seen; anteriorly, at the level of the hard palate, is the anterior nasal spine. Within the hard palate and about 1 cm behind the anterior premaxilla is the incisive foramen. This foramen extends cranially as two separate incisive canals that open on either side of the base of the nasal septum. Together these canals and the foramen form a Y shape on coronal images. These canals transmit the terminal branches of the sphenopalatine arteries and their anastomoses with the terminal branches of the greater palatine arteries. The canals also transmit the nasopalatine nerves.

On coronal images, the palatine spines are seen on the oral surface of the hard palate. Lateral to the spines are the palatine grooves in which run the palatine vessels and nerves. The greater palatine foramen is seen posteriorly at the lateral junction of the lateral hard palate and the maxillary alveolus. The anterior surface of this canal is formed by the maxillary bone, the posterior surface by the palatine bone. Extending upward from the greater palatine foramen toward the pterygopalatine fossa is the pterygopalatine canal. The canal transmits the anterior palatine nerve and the descending palatine artery. Occasionally the lesser palatine foramen may be identified. It also extends to the pterygopalatine fossa and opens just posterior to the greater palatine foramen. The lesser palatine foramen transmits the posterior palatine nerve.

The anterior two thirds of the hard palate on each side is formed by the palatine process of the maxilla, the posterior one third by the horizontal process of the palatine bone. The most posterior medial wall of the antrum is formed by the vertical portion of the palatine bone.

The Pterygopalatine Fossa

The pterygopalatine fossa is a small, thin rectangular space directly behind the perpendicular plate of the palatine bone and in front of the pterygoid process of the sphenoid bone. On axial images it appears that this space is directly posterior to the medial back wall of the maxillary sinus, this observation often leading to the false impression that the anterior wall of the pterygopalatine fossa is formed by the maxillary bone. In actuality, although the palatine bone cannot be separated on images from the maxillary bone, it is the ascending portion, or perpendicular plate of the palatine bone, that forms the anterior wall of the pterygopalatine fossa.

The pterygopalatine fossa communicates with five

Copyright © 2003, Mosby, Inc. All rights reserved.

anatomic areas: (1) the nasal fossa (via the sphenopalatine foramen), (2) the mouth (via the greater and lesser pterygopalatine canals, which open on the palate through the greater and lesser palatine foramina), (3) the infratemporal fossa (via the retromaxillary space or fissure), (4) the orbit (via the inferior orbital fissure), and (5) the intracranial compartment and skull base (via the pterygoid or Vidian canal and the foramen rotundum).

More specifically, the medial boundary of the fossa is formed by the sphenopalatine foramen, which is at the craniocaudal level of the posterior tip of the middle concha, about 1 cm dorsal to it. This foramen may be seen connecting the nasal fossa with the pterygopalatine fossa. Within the pterygopalatine fossa are the sphenopalatine ganglion, portions of the maxillary nerve, and the internal maxillary artery. It is actually the sphenopalatine artery (the terminal branch of the internal maxillary artery) that runs through this foramen. All of these structures are supported by fat, which fills the majority of the pterygopalatine fossa. The nasopalatine nerve (a branch of the sphenopalatine nerve, which is a branch of the maxillary nerve [V_2]), also passes through the sphenopalatine foramen.

Extending posteriorly into the middle cranial fossa via the skull base are two canals. The lower and more medial canal is the pterygoid or Vidian canal, while the upper and more lateral canal is the foramen rotundum/canal. The Vidian canal may be almost entirely within the sphenoid bone or sitting well within the sinus on a septum above the sinus floor. Similarly, the foramen rotundum may protrude into the lateral lower wall of the sphenoid sinus or may be completely lateral to the sinus. More posteriorly, the optic canal may protrude into the upper lateral sinus wall. These sphenoid sinus variations are discussed in detail in Chapter 3.[47]

The Pterygoid Plates

The medial pterygoid plate is almost vertically oriented. The lateral plate is tilted so that its lower end, at the level of the hard palate, is more lateral than its cranial margin at the skull base. The pterygoid fossa lies between these plates. These relationships are often best appreciated on coronal images. The medial or internal pterygoid muscle arises from the medial side of the lateral pterygoid plate within the pterygoid fossa, and the lateral or external pterygoid muscle arises from the lateral side of the lateral plate. The tendon of the tensor veli palatini muscle passes around the laterally concave-shaped hamulus of the lower medial pterygoid plate to form part of the soft palate.

The Nasal Septum

The nasal septum is formed anteriorly to posteriorly by the medial crura of the alar cartilages, the septal cartilage, the perpendicular plate of the ethmoid bone, and the vomer. Inferiorly, the nasal crests of the maxilla and palatine bones contribute to the base of the septum. The posterior edge of the vomer joins the undersurface of the sphenoid bone at the sphenoid rostrum, a prominent triangular ridge on the underbody of the sphenoid bone. In addition to deviations of the nasal septum, nasal spurs can occur on either side. These usually triangular bony excrescences occur at the level of the junction of the perpendicular plate of the ethmoid bone and the vomer.

The Olfactory Recesses and Nasal Atrium

The olfactory recess is the narrow channel-like region of the nasal cavity on either side of the upper nasal septum. These spaces continue up to the cribriform plate. On either side, the olfactory recess widens posteriorly into the sphenoethmoidal recess. This marks the junction between the ethmoid and sphenoid bones.

In the anterior lateral nasal cavity, just below and medial to the agger nasi cells, is the region referred to as the nasal atrium. This atrium region is continuous with the more posterior nasal fossa (see Chapter 3).

The Margins of the Orbit

On coronal images through the superior orbital rims, a localized notch, or foramen, can be seen along the medial orbital margin. This is the supraorbital notch (or foramen), and the supraorbital artery and nerve pass through it. Medial to the supraorbital notch is the frontal notch, which transmits the frontal artery and the frontal nerve. Although the orbital surface of the orbital roof is smooth, the intracranial margin of the orbital roof has bony ridges that, in a general way, reflect the impressions of the gyri of the base of the frontal lobes.

Along the medial orbital walls are the anterior ethmoidal canals, which are seen as medial indentations in the upper lamina papyracea. They transmit the anterior ethmoidal nerves and vessels. The lower margins of these canals are formed by the ethmoid bones, and the upper margins are formed by the frontal bones. More posteriorly are the similarly formed posterior ethmoidal canals, which transmit their respective vessels and nerves.

In the middle third of the orbital floor are the infraorbital foramen and canal. The canal extends from the inferior orbital fissure posteriorly to the anterior maxilla. This canal runs parallel to the orbital floor except in its most anterior portion, where, starting about 1 cm behind the inferior orbital rim, it turns downward to exit as the infraorbital foramen about 1 cm below the inferior orbital rim on the anterior face of the maxilla.

The inferior orbital fissure is about 2 cm long and is angled at about 45° (open anteriorly) with the midsagittal plane. This fissure is narrowest in its midportion and widens at both its medial and lateral margins. This fissure separates the lateral orbital wall from the orbital floor, and at the lateral posterior margin of the inferior orbital fissure the temporal fossa becomes the infratemporal fossa.

The circular configuration of the anterior orbit slowly changes to a more triangular shape in the posterior orbit. This change in shape occurs because the medial orbital floor elevates, and the lower lamina papyracea tilts laterally, as the larger posterior ethmoid cells are encountered.[47]

The thin lacrimal bone has a slightly concave lateral configuration, forms the anterior medial orbital wall, and overlies the anterior ethmoid cells. The ethmoid lamina

Copyright © 2003, Mosby, Inc. All rights reserved.

papyracea, which lies just behind the lacrimal bone, tends to be even thinner and has a straighter configuration than the lacrimal bone.

The Lacrimal Fossa and Nasolacrimal Duct

The fossa for the lacrimal gland is a shallow, smooth indentation in the frontal bone along the upper outer aspect of the orbital roof. The lacrimal groove is in the lower medial orbital wall and is related to the lacrimal sac of the nasolacrimal system. It is actually preseptal in location and not in the orbit, being anterior to the posterior lacrimal crest. The lacrimal groove is also anterior to the nasolacrimal canal, which lies in the medial antral wall. This reflects the anatomy of the nasolacrimal canal, which runs downward and posteriorly at about a 20° angle with the coronal plane. On imaging, the lacrimal groove creates a normal ''dehiscence'' in the medial orbital floor that should not be confused with a focal site of erosion. The caudal opening of the nasolacrimal canal is in the medial antral wall under the inferior turbinate (lateral wall of the inferior meatus). The medial wall of the nasolacrimal canal is formed superiorly by the lacrimal bone and inferiorly by the lacrimal process of the inferior turbinate. The lateral wall is formed entirely by the maxilla. See Chapter 10.

The Sphenoid Sinus Septum

The sphenoid intersinus septum is usually in the midline anteriorly, but posteriorly it may be angulated sharply to one side. This creates two unequally sized sinuses, and once the scan plane moves posterior to such an angled septum, it will appear as if there is only one sphenoid sinus cavity. In the floor of the sinus runs the Vidian canal. This canal may lie entirely within the sphenoid bone or may be elevated by a septum and lie within the lower sinus cavity. The foramen rotundum anteriorly and the optic canal posteriorly can also be partially within the lateral sinus wall. If any of these canals do project into the sinus cavity, or if there is dehiscence of the bony wall separating the canal from the sinus, injury to the nerve can occur during sinus surgery. This topic is discussed further in Chapter 3.

The Maxillary Sinus Walls

The medial wall of the maxillary sinus is partially bone and partially membrane. This membranous area forms a C shape, which is closed posteriorly and bridges the posterior attachment of the inferior turbinate. The anterior wall of the maxillary sinus has a slightly concave anterior configuration, with the concavity marking the site of the canine fossa. This fossa lies cranial to the lateral incisor and canine teeth and caudal to the infraorbital canal, and the caninus muscle arises in it. The posterior sinus wall is curved and sigmoid-shaped, and the infratemporal fossa fat abuts its posterior surface. Within the posterolateral antral wall there is a thin canal for the posterosuperior alveolar nerve. This canal should not be confused with a site of bone erosion or a fracture.

THE INTEGUMENT OF THE FACE AND SCALP

The facial bones, calvarium, and contained spaces receive the primary attention of the imager. However, in a limited way, the overlying skin, muscles, nerves, and vessels that supply them are also seen on images of the sinonasal cavities and head. The following sections briefly review the muscles, nerves, arteries, and veins that involve the face and scalp.[6]

The Facial Muscles

The facial muscles can be thought of as connecting bone and skin. These muscles are responsible for facial expression, and they create tension lines (Langer's cleavage lines) in the skin that are oriented at right angles to the plane of the muscle fibers. These tension lines, which deepen with age as the skin loses its elasticity, can be used to hide surgical incisions. These muscles are summarized in Table 2-1. The nasal muscles have already been discussed in the section on The Nose and Nasal Fossae[63, 64] under the heading of ''Anatomy and Physiology.''

An important concept to understand is that the mimetic muscles of the face, including the platysma, are interconnected by a fibrous aponeurosis called the superficial musculoaponeurotic system (SMAS). This system divides the subcutaneous fat into two layers and acts as a tensor of the facial muscles (see also Chapter 34).

Scalp and Forehead

On the scalp and forehead are the occipital and frontal bellies of the occipitofrontal (epicranius) muscle and the corrugator supercilii muscle. The occipital belly elevates the skin of the forehead, and the frontal belly pulls the skin toward the eyebrow. The corrugator supercilii draws the brow medially, creating frown lines near the glabella. There is the temporoparietalis muscle, which draws the skin back from the temple region and tightens the scalp. There are also small muscles (auriculares anterior, superior, and posterior) that are related to the ear and that retract and elevate the ear. The layers of the scalp include the skin, the superficial fascia or tela subcutanea (in which runs most of the blood vessels and cutaneous nerves), the epicranial aponeurosis or gala aponeurosis, loose connective tissue, and the cranial periosteum or pericranium.

Orbit

About the eye is the orbicularis oculi, which is composed of a series of concentric muscular rings. Closure of the eye is the result of coordinated contraction of the entire muscle. Blinking involves only the palpebral region of the muscle. This palpebral portion of the muscle attaches posterior to the medial palpebral ligament and aids in pumping tears from the lacrimal sac.

Copyright © 2003, Mosby, Inc. All rights reserved.

Cheek and Lips (Mouth)

In the region of the cheek and lips (mouth), the buccinator muscle serves to compress the cheeks, to help expel air, and to aid in mastication. As such, it is more a muscle of mastication than a muscle of facial expression. The orbicularis oris acts to compress, contract, and protrude the lips. Elevation of the upper lip is caused by the levator labii superioris and the levator labii superioris alaeque nasi muscles, while the levator anguli oris muscle elevates the angle of the lip. Similarly, the lower lip has the depressor labii inferioris (irony) muscle and the depressor anguli oris (grief) muscles. The lesser (minor) and greater (major) zygomaticus muscles elevate the angle of the mouth (laughing), and the lesser zygomaticus muscles help produce the nasolabial fold. The risorius muscle retracts the angle of the mouth (grinning). The mentalis muscle raises and protrudes the lower lip and wrinkles the skin (disdain). The transverse menti muscle is present in about 50% of people; it crosses the midline just under the chin. Lastly, the platsyma muscle assists in depressing the lower jaw and lip and tenses the skin of the neck. These facial muscles are summarized in Figure 2-51.

Cutaneous Innervation of the Face

On a lateral projection of the head and face, a line drawn from the vertex of the head to the tip of the chin defines a plane. The cutaneous innervation of the skin and head by the trigeminal nerve is anterior and above this plane; the cutaneous distribution of the cervical nerves is posterior and below this line. The trigeminal distribution follows the major branches of this nerve. Thus, the first division supplies the upper nose to its tip, around the medial, upper, and lateral orbits, and the upper scalp. The second division of the trigeminal nerve supplies the lateral nose, upper lip, and skin between the nose and mouth. It also supplies the skin over the malar eminence of the zygoma and a tapering triangle of skin along the anterior side of the scalp. The third division supplies the lower lip, chin, lateral face to the level of the lower mandibular border, and lateral scalp up to the line drawn from the vertex to the chin tip. The superficial cervical plexus supplies the ear, periauricular region, and anterior neck. The posterior divisions of the cervical nerves supply the posterior scalp and neck. These cutaneous nerves derive from the second, third, and fourth cervical nerves as they form the cervical plexus. The superficial cutaneous branches include the smaller occipital nerve (C2), the greater auricular nerve (C2 and C3), the cervical cutaneous nerve (C2 and C3), and the supraclavicular nerve (C3 and C4). These areas are summarized in Figure 2-52.

Arterial Supply of the Face and Scalp

The vascular supply of the face and head comes from branches of both the external and internal carotid arteries. The branches from the internal carotid artery are terminal branches of the ophthalmic artery, the supratrochlear and supraorbital arteries. They supply the upper periorbital region and immediate forehead. The major branches of the external carotid artery are the superficial temporal artery (supplies most of the forehead and scalp), the transverse facial artery (supplies the lateral face), the facial artery (supplies the central and lower portions of the face), the posterior auricular artery (supplies the back of the auricle or pinna and the periauricular region), and the occipital artery (supplies the posterior scalp, upper posterior neck, auricle, and a meningeal branch that enters the skull through the jugular foramen and supplies the dura of the posterior fossa).[63–65] These relationships are summarized in Figure 2-53.

Venous Drainage of the Face and Scalp

The drainage of the face is primarily via the facial vein and the retromandibular vein. The frontal vein begins in a venous plexus in the forehead that anastomoses with the superficial temporal vein. The frontal vein then descends to the root of the nose, where the nasal arch vein joins the parallel frontal vein of the opposite side. The supraorbital vein runs down the forehead and anastomoses with the frontal vein near the medial canthus to form the angular vein. The angular vein runs down the side of the nose in the nasolabial fold to the level of the lower orbit or bottom of the nose, where it becomes the anterior facial vein, which drains the blood from the nose and lips. It then follows the course of the facial artery down across the face, over the mandible, to join the common facial vein that drains into the internal jugular vein near the level of the hyoid bone. The anterior facial vein is joined by the superior and inferior palpebral veins, the superior and inferior labial veins, the buccinator vein, and the masseteric vein.

The superficial temporal vein starts in the scalp in a venous plexus that communicates with the frontal and supraorbital veins, the opposite superficial temporal vein, and the posterior auricular and occipital veins. Frontal and parietal veins join and then are in turn joined above the zygomatic arch by the middle temporal vein, which receives tributaries from orbital veins. This vein is then joined by the maxillary vein draining the infratemporal fossa. The pterygoid plexus drains the sphenopalatine, middle meningeal, deep temporal, pterygoid, masseteric, buccinator, alveolar, and some palatine veins and communicates via the inferior orbital fissure with the ophthalmic vein. It also communicates with the facial vein and cavernous sinus. Together the superficial temporal vein and the internal maxillary vein form the retromandibular vein, which receives tributaries from the parotid and auricular veins and from the transverse facial vein. At the lower margin of the parotid gland, the retromandibular vein joins the common facial vein and also anastomoses with the external jugular vein. The posterior auricular vein communicates with the superficial temporal and occipital veins and descends behind the auricle to join the posterior facial vein and form the external jugular vein. The occipital vein begins as a plexus at the back of the vertex of the scalp and as a single vein descends into the suboccipital triangle, where it is joined by the deep cervical and vertebral veins. It can join the internal jugular vein directly or join the posterior auricular vein. The occipital vein receives the parietal emissary vein, which communicates with the superior sagittal sinus and the mastoid emissary vein, which communicates with the transverse sinus. The veins of the forehead and upper lids drain into the orbit and the inferior and superior branches of the ophthalmic vein.[63–65] The relationships are summarized in Figure 2-53.

ZB	Zygomatic Bone
Zyg Arch	Zygomatic Arch
ZygoTemp Can	Zygomaticotemporal Canal

Within the axial anatomic atlas, Figures 10A, B, and C show variations in the size of the sphenoid sinuses with lateral and pterygoid recesses. Figure 21A shows an alveolar recess of the maxillary sinus, with the sinus extending caudal to the hard palate. Figures 21B and C show the incisive canals and the incisor foramen.

Within the coronal anatomic atlas, Figure 10 shows variations in the pneumatization of the lower maxillary sinus. Figure 10A shows palatal recesses. Figure 10B shows lack of pneumatization of the maxillary alveolus. Figure 10C shows pneumatization of the inferior turbinate. Figure 11 shows a typical example of a torus palatinus and maxillary exostoses. Axial Figure 16A and coronal Figure 11B show pneumatization of the inferior turbinate by the maxillary sinus. Figures 14-17 show variations in sphenoid sinus configuration and the location of the foramen rotundum and Vidian canals near and within the sinus. Axial and coronal Figures 1B show frontal sinus pneumatization of the orbital roofs. The presence of bone between the ethmoid complex and the recess differentiates these from supraorbital ethmoid cells.

OPERATIVE COMPLICATIONS

HISTORIC PERSPECTIVE

Sinonasal inflammatory disease is a serious health problem that affects an estimated 30 to 50 million people in the United States.[1] Traditionally, plain films were the modality of choice in evaluation of sinus pathology. Clinical and radiographic emphasis was directed primarily to the maxillary and frontal sinuses. In recent years, it has become evident that sinusitis is primarily a clinical diagnosis. The role of imaging is to document the extent of disease, to answer questions regarding ambiguous cases, and to provide an accurate display of the anatomy of the sinonasal system.

Copyright © 2003, Mosby, Inc. All rights reserved.

Imaging now provides the surgeon with a detailed ''road map'' for guiding the functional endoscopic sinus surgery procedure. Today, computed tomography (CT) is the modality of choice for the imaging evaluation of the morphology in this area.

Although most patients with sinonasal inflammatory disease are initially treated medically, the disease often does not resolve. Patients with persistent disease usually require surgical intervention, and the surgical treatment of refractory inflammatory sinus disease has undergone revolutionary changes in the last 10 to 20 years. These advances are due to an improved understanding of the mucociliary clearance pathways in the nasal cavity and paranasal sinuses, improved endoscopes that afford direct access to nasal cavity and ethmoid sinus drainage portals, and the availability of high-resolution coronal CT images that provide an accurate display of the regional anatomy.

Functional endoscopic sinus surgery (FESS) was first described independently by both Messerklinger in the German literature and Wigand, Steiner, and Jaumann in the English literature in 1978.[2–4] FESS was introduced in the United States in 1984 by Kennedy et al., and subsequent evolution of the technique has occurred through innovations in both the surgical and radiologic fields.[5, 6]

This chapter will discuss the imaging modalities available for patients with surgically amenable inflammatory sinus disease and describe the pertinent imaging anatomy and anatomic variants of the paranasal sinuses and adjacent structures, review the radiographic appearance of inflammatory sinus disease and describe FESS procedures.

TECHNIQUES OF EVALUATION

Plain Films

The standard plain film sinus series usually consists of four views: lateral, Caldwell, Waters, and submentovertex. The anatomy displayed on each of these views is reviewed in Chapter 2.[7] Although the standard radiographs may be accurate in showing air-fluid levels, the degree of chronic inflammatory disease present is consistently and significantly underestimated. Furthermore, the superimposition of structures precludes the accurate evaluation of the anatomy of the ostiomeatal channels, with which the modern surgeon needs to be familiar.[6, 8–11]

Computed Tomography

CT is currently the modality of choice in the evaluation of the paranasal sinuses and adjacent structures.[6, 8–11] Its ability to optimally display bone, soft tissue, and air provides an accurate depiction of both the anatomy and the extent of disease in and around the paranasal sinuses.[6, 8–11] In contrast to standard radiographs, CT clearly shows the fine bony anatomy of the ostiomeatal channels.

Many authors stress the importance of performing the initial CT scan after a course of adequate medical therapy to eliminate or diminish reversible mucosal inflammation. Several authors also suggest routine pretreatment with a sympathomimetic nasal spray 15 minutes prior to scanning in order to reduce nasal congestion (mucosal edema) and thus improve the display of the fine bony architecture and any irreversible mucosal disease.[12]

The coronal plane best shows the ostiomeatal unit (OMU), shows the relationship of the brain to the ethmoid roof, and correlates closely with the surgical orientation. Thus, the coronal plane should be the primary imaging orientation for evaluation of the sinonasal tract in all patients with inflammatory sinus disease who are endoscopic surgical candidates.[6–8, 11] This can be accomplished by direct coronal scanning or by reformatting data acquired in the axial plane into coronal plane images.

If direct scanning is done, the coronal study optimally should be performed in the prone position so that any remaining sinus secretions do not obscure the OMU. In patients who cannot tolerate prone positioning (children, patients of advanced age, etc.), the hanging head technique can sometimes be utilized. In this technique, the patient is placed in the supine position and the neck is maximally extended. A pillow placed under the patient's shoulders facilitates positioning. The CT gantry is then angled to be perpendicular to the hard palate. However, it is not always possible to obtain true direct coronal images with this technique.

Patients who are intubated or have tracheostomy tubes usually cannot tolerate positioning for coronal scans. Similarly, young children, patients with severe cervical arthropathy, and patients who are otherwise debilitated often cannot tolerate direct coronal positioning. In such patients, spiral scanning or thin section, contiguous axial CT images with coronal reconstructions are performed.

Axial images complement the coronal study, particularly when there is severe disease (opacification) of any of the paranasal sinuses and surgical treatment is contemplated. The axial studies are needed, as the posterior walls of various sinuses are not well seen, if at all, in the coronal plane. Axial images are particularly important in visualizing the frontoethmoid junction and the sphenoethmoid recess.

Today spiral CT offers the advantage of speed and the ability to generate very thin images. With the use of double spiral scanners or multidetector technology, the slice thickness can be reduced to 0.5 mm or less. For the pediatric, elderly, and debilitated patients who may not be able to remain still for prolonged periods of time, this technique offers the best opportunity to acquire a motion-free, high-quality study. The patient may be positioned prone with the head hyperextended or supine with the head in neutral position on the scanning table. Given the ability of spiral CT to generate very thin images, the quality of reconstructed coronal and/or sagittal images is virtually indistinguishable from that of images obtained in the primary scan plane. In phantom studies performed with the parameters outlined in Box 3-1, a lens dose of 14 mGy was measured for scanning the paranasal sinuses in either the axial or coronal position.[13]

The recent introduction of multidetector CT scanners has allowed even more refined reconstructions in planes other than the primary scan plane. Motion and reconstruction artifacts may still create very minor image degradation, but this is offset by the lack of obscuration of important anatomy by ''spray'' artifact from dental restorations. Since the original data set is acquired in the axial plane, the important

VIEW IMAGE

FIGURE 3-1 CT lateral topogram shows the patient's position during the examination. Dotted lines represent the scanner gantry angulation, which should be as perpendicular as possible to the hard palate (*arrows*).

anatomy of the OMU is not imaged at the same time as the metallic restorations, so the artifact is projected well away from the crucial landmarks. This multidetector scanner most likely will become the scanner of choice for imaging the sinonasal cavities.

Examination Protocol

For direct coronal scanning, the patient is placed prone on the scanner table, with the chin hyperextended. The scanner gantry is angled perpendicular to the hard palate (Fig. 3-1). The angulation of the scan plane is very important, as Melhem et al. noted that variations in scan angulation greater than 10° from the plane perpendicular to the hard palate result in significant loss of anatomic detail of the structures of the OMU.[14]

Scanning is performed as contiguous 3-mm-thick images from the anterior wall of the frontal sinus through the posterior wall of the sphenoid sinus. Contiguous scans are essential to avoid loss of information through ''skipped'' areas.[14] The field of view should be adjusted to include only the areas of interest. This not only helps reduce artifact from the teeth and associated metallic restorations, but magnifies the small anatomic structures of the nasal cavity and adjacent paranasal sinuses.[9]

The original exposure settings for sinus CT were 125 kVp, 450 mAs, and 5-second scan time. However, Babbel et al. showed that there was no compromise of image quality when the milliampere-second (mAs) setting was reduced to 200 mAs (2-second scan time), and recent work by Melhem et al. showed no significant loss of diagnostic quality with mAs settings of 160 or even 80 mAs (2-second scan time).[12, 14] It is therefore recommended that the exposure settings be 125 kVp and 80 to 160 mAs. Box 3-1 summarizes the sinus CT examination protocol.[10]

SUMMARY BOX 3-1

Parameters for Sinus CT

Patient position	Prone
Angulation	Perpendicular to hard palate
Field of view	14 cm
Thickness	3 mm, contiguous
Exposure	125 kVp and 80–160 mAs

Radiation Exposure

To review briefly, the radiation exposure (dose) that a patient receives is known as the radiation-absorbed dose. This dose is a measure of the total radiation energy absorbed by the tissues, and it is expressed in an SI unit known as the *Gray* (Gy). One Gy is the amount of radiation needed to deposit the energy of 1 joule (J) in 1 kg of tissue (Gy = 1 J/kg). Formerly, the unit used to express the radiation-absorbed dose was the *rad* (1 rad = amount of radiation needed to deposit the energy of 100 ergs in 1 g tissue). The conversion of the rad to the Gy is: 1 Gy = 100 rad.[15, 16]

A more useful term is *radiation dose equivalent*, which takes into account the quality factor Q of the radiation (radiation dose equivalent = radiation dose absorbed × Q). This quality factor accounts for the varying biologic effectiveness of different forms of ionizing radiation. For x-rays, $Q = 1$; thus, the radiation-absorbed dose is equivalent to the radiation dose equivalent. Currently the SI unit of radiation dose equivalent is the *Sievert* (Sv); the former unit was the *rem*. Therefore, for diagnostic x-rays, 1 Gy = 1 Sv and 1 Sv = 100 rem.[15, 16]

The radiation dose equivalent is dependant on the kilovolt peak (kVp) and mAs. For a given kVp, the radiation dose equivalent varies linearly with the mAs. At 125 kVp the radiation dose equivalent for a CT slice is approximately 1.1 to 1.2 cSv/100 mAs (1.1 to 1.2 rem/100 mAs). The actual dose varies slightly from machine to machine. Table 3-1 shows that the radiation dose equivalent for a CT slice can be considerably reduced using a low mAs technique.[10]

In contiguous CT imaging, the dose delivered to a particular region scanned (for example, the paranasal sinuses) is approximately equal to the per-slice dose. The dose delivered to a region is less than the per-slice dose if

Table 3-1
RELATIVE RADIATION DOSE FOR SINUS CT (UTILIZING 125 kVp)

mAs	Radiation Dose Equivalent
450	4.95–5.40 cSv (4.95–5.40 rem)
240	2.64–2.88 cSv (2.64–2.88 rem)
160	1.76–1.92 cSv (1.76–1.92 rem)
80	0.88–0.96 cSv (0.88–0.96 rem)

there is a gap between slices, and the delivered dose is higher if there is overlap between slices.

Image Display

The effective dose equivalent was developed as a way of representing the fraction of the total stochastic risk of fatal cancers and chromosomal abnormalities resulting from the irradiation of a particular organ or tissue when the body is uniformly irradiated.[15, 16] A system of weighting is used to take into account the individual sensitivity of the body's major tissues and organs.[15, 16] A full discussion of the effective dose is beyond the scope of this chapter. Suffice it to say that for a given examination, the effective dose to the patient is less than the dose (radiation dose equivalent) received by the area scanned. A list of effective dose equivalents for some common radiographic procedures is presented in Table 3-2.[15, 17]

Windows are chosen to highlight the air passages, the bony detail, and the soft tissues. Usually a window width of +2000 Houndsfield units (HU) and a level of −200 HU are good starting parameters. The window and level settings can then be manipulated manually to display optimally the anatomic detail of the uncinate process and ethmoid bulla. Once this is accomplished, these settings can be used to film the entire study.[6, 8–11]

Sagittal reconstructions can be obtained for a morphologic orientation, and various distances and angles can be measured to aid in the passage of instruments during surgery. If only coronal scans are obtained, axial reconstructions can help display the position of the internal carotid arteries and optic nerves with respect to the bony margins of the posterior ethmoid and sphenoid sinuses.

Magnetic Resonance Imaging

Although magnetic resonance (MR) imaging provides better visualization of soft tissue than CT, its disadvantage is its inability to display optimally the cortical bone–air interface.[9, 10] Because both cortical bone and air have signal voids, at times MR imaging is unable to discern the intricate anatomic relationships of the sinuses and their drainage portals. Thus, MR imaging cannot be reliably used as an operative road map to guide the surgeon during FESS.

NASAL CYCLE

There is a side-to-side cyclic variation in the thickness of the nasal mucosa known as the nasal cycle (see Chapter 2), and the signal intensity of the mucosal lining of the nasal cavity and the ethmoid sinuses varies in concert with the nasal cycle.[18, 19] Thus, during the edematous phase of the nasal cycle, the mucosal signal intensity on T2-weighted images is similar to the appearance of mucosal inflammation, limiting the usefulness of MR imaging in these patients (Fig. 3-2).[11, 12] Interestingly, there is no cyclic variation of the mucosal signal in the frontal, maxillary, or sphenoid sinuses, and increased mucosal thickness and increased signal on T2-weighted images in these sinuses are always abnormal.[18, 19] To date, with respect to the paranasal sinuses, MR imaging has proven most helpful in the evaluation of the regional and intracranial complications of inflammatory sinus disease, in identifying complications of its surgical treatment, and in mapping neoplastic diseases (see Chapters 5 to 7).[20–24]

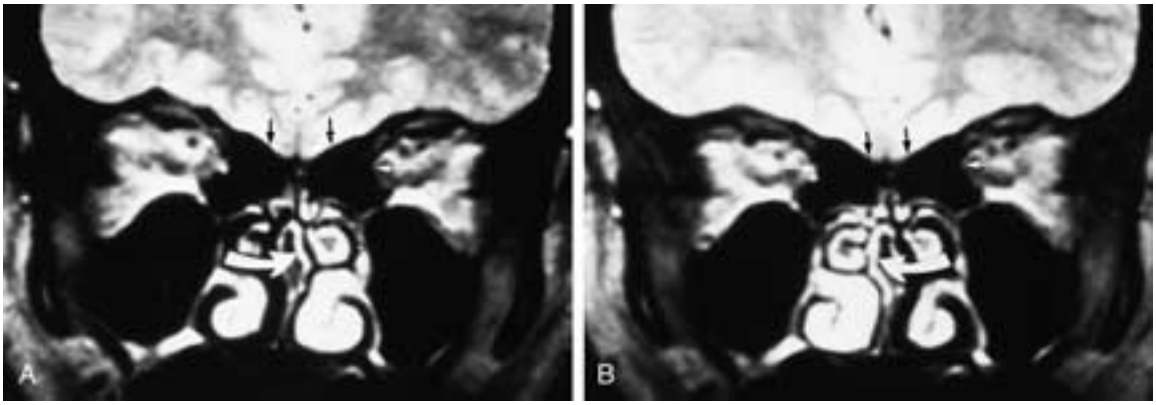

FIGURE 3-2 Nasal cycle on MR imaging. **A** and **B**, Coronal T2-weighted MR images of the anterior ethmoid sinuses show the changing edema of the nasal cavity (*curved arrow*), the ethmoid sinus mucosa, and the changing size of the turbinates. Note the lack of signal for definition of the ethmoid sinus roof and lamina papyracea (*arrows*).

INTERPRETATION OF IMAGING STUDIES

In any imaging study, the radiologist must use a variety of skills to provide consistent, accurate interpretations. With regard to the paranasal sinuses, these skills include the following:

1. Detailed knowledge of the anatomy of the paranasal sinuses
2. Systematic reading pattern
3. Detailed knowledge of the common pathologies affecting the region
4. Working knowledge of the available surgical options and their radiographic appearance
5. Awareness of common operative complications and their radiographic appearance

NORMAL ANATOMY

Mucociliary Clearance

An understanding of the regional anatomy and the importance of the anterior ethmoid sinus structures is critical if one is to understand the flow pattern of the mucous blanket coating the paranasal sinuses. The movement of this mucous blanket is referred to as mucociliary clearance. Further, one must be acquainted with the concept that inflammatory sinus disease results primarily from interference of mucociliary clearance due to compromise of the drainage portals (ostiomeatal channels) of the individual sinus cavities.

The mucosa of the paranasal sinuses and nasal fossae is made up of a ciliated cuboidal epithelium that secretes mucus. This mucus covers the epithelium and, as such, is referred to as a mucous blanket. The cilia are in constant motion and act in concert to propel the mucus in each sinus toward the sinus ostium and then, once in the nasal fossae, back toward the pharynx (see also Chapter 2). The pattern of flow is specific for each sinus and persists even if alternative openings are surgically created in the sinus.[25–27] One of the reasons that FESS has gained such wide acceptance is that its goal is to restore sinus drainage via the normal anatomic drainage pathways, thus allowing normal mucociliary clearance.

In the maxillary sinus, mucous flow originates in the antral floor and is then directed centripetally toward the primary ostium. The mucus is then transported through the infundibulum to the hiatus semilunaris, whence it passes into the middle meatus and ultimately into the nasopharynx. This pattern of mucus movement persists even after a nasal antrostomy is created.[25–27]

In the frontal sinus, the mucus flows up along the medial wall, laterally across the roof, and medially along the floor. As the flow approaches the medial aspect of the floor, some is directed into the primary ostium and the remainder is recirculated. The cleared mucus travels down the frontal recess and then into the middle meatus, where it joins the flow from the ipsilateral maxillary sinus.[25–27]

The posterior ethmoid and sphenoid sinuses clear their mucus into the sphenoethmoidal recess. The flow then enters the superior meatus and subsequently the nasopharynx.

Thus, there are two main ostiomeatal channels. The anterior OMU includes the frontal sinus ostium, frontal recess, maxillary sinus ostium, infundibulum, and middle meatus. These channels provide communication between the ipsilateral frontal, anterior ethmoid, and maxillary sinuses. The posterior OMU consists of the sphenoid sinus ostium, the sphenoethmoidal recess, and the superior meatus. The imaging investigation of these regions should be directed to optimally display these ostiomeatal channels.

Normal Anatomy (Ostiomeatal Unit)

Correct interpretation of sinonasal imaging studies requires an understanding of the anatomy of the lateral nasal wall and its relationship to adjacent structures (Fig. 3-3).[28, 29] The lateral nasal wall contains three bulbous projections: the superior, middle, and inferior turbinates (conchae). The turbinates divide the nasal cavity into three distinct air passages: the superior, middle, and inferior meati. Each respective meatus is lateral to its corresponding turbinate. The superior meatus drains the posterior ethmoid air cells and, more posteriorly, the sphenoid sinus (via the sphenoethmoidal recess). The middle meatus receives drainage from the frontal sinus (via the frontal recess), the maxillary sinus (via the maxillary ostium and subsequently the ethmoidal infundibulum), and the anterior ethmoid air cells (via the ethmoid cell ostia). The inferior meatus receives drainage from the nasolacrimal duct.

The imaging evaluation of the morphology of this area should focus on the anatomic structures surrounding three specific ‘‘tight spots.’’ Anteriorly, the first area comprises the structures surrounding the frontal recess. The second area consists of the structures surrounding the infundibulum and middle meatus. The third and most posterior area includes the anatomic structures surrounding the sphenoethmoid recess. Summary Boxes 3-2, 3-3, and 3-4 outline the individual anatomic structures found in each of these tight spots.

On CT scanning, the first coronal images display the outline of the frontal sinuses (Fig. 3-4). The frontal sinuses have an overall funnel shape, and their aeration varies from patient to patient and from side to side in individual patients. Some sinuses are small and occupy only the diploic space of the medial frontal bone, while other sinuses can be large enough to extend through the floor of the entire anterior cranial fossa. In general, a central septation separates the left and right sides; however, often there may be several septations. The floor of the frontal sinus slopes inferiorly toward the midline.

Close to the midline, the primary ostium is located in a depression in the floor. The frontal recess is an hourglass-like narrowing between the frontal sinus and the anterior middle meatus through which the frontal sinus drains (Figs. 3-5 to 3-7).[8] It is not a tubular structure, as the term *nasofrontal duct* might imply, and therefore the term *recess* is preferred.

Anterior, lateral, and inferior to the frontal recess is the agger nasi cell. This cell is a remnant ethmoturbinal and is present in nearly all patients. It is aerated and represents the most anterior ethmoid air cell, usually lying deep to the lacrimal bone. It usually borders the primary ostium or floor of the frontal sinus, and thus its size may directly influence

the patency of the frontal recess and the anterior middle meatus. The frontal recesses are the narrowest anterior air channels and are common sites of inflammation. Their obstruction subsequently results in loss of ventilation and mucociliary clearance of the frontal sinus.

Frontal Cells

Frontal cells are invariably found in relation to the anterior ethmoid air cells and the agger nasi cell (Fig. 3-7). The recognition and subsequent definition of the appearance and etiology of frontal cells was initiated by J. Parson Schaeffer. During the course of his observations of the embryonic development of the sinuses, he discovered that it is possible, although infrequent, for one cell to aerate each half of the frontal bone, each with a separate communication to the frontal recess. Schaeffer coined the term *frontal cell* to describe this phenomenon.[30, 31] Van Alyea subsequently defined the frontal cell as a cell encroaching on the frontal recess or frontal sinus.[32–34] He considered supraorbital ethmoid, agger nasi, and intersinus septal cells, as well as cells limited to the frontal recess, as frontal cells. Bent et al.[35] defined frontal cells more specifically as belonging to one of four categories, detailed in Table 3-3. They also stated that all frontal cells derive from the anterior ethmoid sinus behind the agger nasi cell and pneumatize the frontal recess above the agger nasi cell. Each type of frontal cell may obstruct the nasofrontal communication or the frontal sinus itself.

FIGURE 3-4 Anatomy of the frontal sinus. Coronal CT images of the frontal sinuses from anterior (**A**) to posterior (**D**) show the relationship between the frontal sinus (*F*) and the middle meatus (*dotted line*). Note that there is a bony strut (*heavy black arrow* in **A** and **B**) separating the frontal sinus and the anterior middle meatus. This separation is lost on the more posterior images (**C** and **D**) revealing the position of the frontal recess (*white arrow*). Note the position of the frontal cell (*A*) and its relationship to the frontal recess. Nasal septum (*S*), ethmoid bulla (*B*), middle turbinate (*T*), and concha bullosa (*C*).

The uncinate process is a superior extension of the lateral nasal wall (medial wall of the maxillary sinus).[8, 10] Anteriorly, the uncinate process fuses with the posteromedial wall of the agger nasi cell and the posteromedial wall of the nasolacrimal duct. The uncinate process has a ''free'' (unattached) superoposterior edge. Laterally this free edge delimits the infundibulum (Fig. 3-8). The infundibulum is the air passage that connects the maxillary sinus ostium to the middle meatus. Posterior to the uncinate process is the ethmoid bulla, usually the largest of the anterior ethmoid cells. The uncinate process usually courses medial and inferior to the ethmoid bulla. The ethmoid bulla is enclosed laterally by the lamina papyracea.

The gap between the ethmoid bulla and the free edge of the uncinate process defines the hiatus semilunaris. Medially, the hiatus semilunaris communicates with the middle meatus, the air space lateral to the middle turbinate.[8, 10] Laterally and inferiorly, the hiatus semilunaris communicates with the infundibulum, the air channel between the uncinate process (caudal border) and the inferomedial margin of the orbit (cranial border). The infundibulum serves as the primary drainage pathway from the maxillary sinus.[10, 11]

SUMMARY BOX 3-4

Sphenoethmoid Recess "Tight Spot" Anatomy

- Superior turbinate
- Posterior ethmoid sinus
- Primary ostium of sphenoid sinus
- Sphenoid sinus
- Optic nerve
- Carotid canal
- Foramen rotundum
- Vidian canal

The structure medial to the ethmoid bulla and the uncinate process is the middle turbinate. Anteriorly it attaches to the medial wall of the agger nasi cell and the superior edge of the uncinate process. Superiorly it adheres to the lateral edge of the cribriform plate. As it extends posteriorly, the middle turbinate emits a number of posterolaterally coursing bony structures. The first such ''laterally fanning'' attachment to the lamina papyracea is the basal lamella, which is posterior to the ethmoid bulla (Figs. 3-9, 3-10). This bony structure serves to separate the anterior and posterior ethmoid cells.

In most patients, the posterior wall of the ethmoid bulla is intact, and an air space is usually found between the basal lamella and the posterior ethmoid bulla. This air space, the sinus lateralis, may extend superior to the ethmoid bulla and

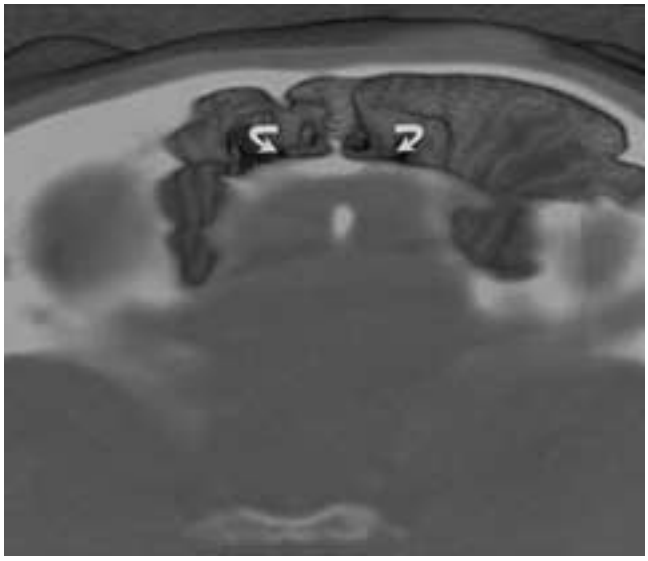

FIGURE 3-5 3D image of the floor of the frontal sinus. The roof of the frontal sinus is removed to demonstrate the floor of the frontal sinus, with emphasis on displaying the location of the frontal recess (*curved arrows*).

VIEW IMAGE

communicate with the frontal recess (Fig. 3-11). Recently, the sinus lateralis has been renamed by an international surgeon's group and is now called the retrobullar recess cell.[36] If it extends above the ethmoid bulla, this extension would be called the suprabullar recess cell. A dehiscence or total absence of the posterior wall of the ethmoid bulla is common and may provide communication between these two usually separated air spaces.

The posterior ethmoid sinus consists of air cells between the basal lamella and the sphenoid sinus. The number, shape, and size of these air cells vary significantly from person to person.[8, 9, 11, 37]

The sphenoid sinus is the most posterior sinus. It is usually embedded in the clivus and is bordered superoposteriorly by the sella turcica. Its ostium is located medially in the anterosuperior portion of the anterior sinus wall and communicates with the sphenoethmoidal recess and the posterior aspect of the superior meatus. The sphenoethmoidal recess lies just lateral to the nasal septum and can sometimes be seen on coronal images, but it is best displayed in the sagittal and axial planes (Figs. 3-12, 3-13).[8, 10]

The relationship between the aerated portion of the sphenoid sinus and the posterior ethmoid sinus must be accurately demonstrated so that the surgeon can avoid operative complications (Fig. 3-14). Usually in the paramedian sagittal plane, the sphenoid sinus is the most superior and posterior air space. Horizontally oriented structures within the sphenoid sinus are actually separations between the posterior ethmoid sinus (Fig. 3-15). All sphenoid sinus septations are vertically oriented. This relationship is well demonstrated on axial and sagittal images. The number and position of the septations in the sphenoid sinus are quite variable, and of particular importance are septations that adhere to the bony canal wall covering the internal carotid artery, which often projects into the posterolateral sphenoid sinus. Less often, the canal of the vidian nerve (pterygoid canal) and the canal of the second division of the trigeminal nerve can project into the floor of the sphenoid sinus.

Anatomically, the paranasal sinuses are in close proximity to the anterior cranial fossa, the cribriform plate, the internal carotid arteries, the cavernous sinuses, the orbits and their contents, and the optic nerves as they exit the orbits.[38–42] The surgeon must be especially cautious when maneuvering instruments directed cranially and dorsally in order to avoid inadvertent penetration and damage to these structures.[6, 11, 40, 41]

ANATOMIC VARIATIONS AND CONGENITAL ABNORMALITIES

Even though nasal anatomy varies significantly from patient to patient, there are some specific variations that occur repeatedly within the population. The prevalence of these variations, as reported by several groups of investigators, are outlined in Summary Box 3-5.[43–53] Certain anatomic variations are thought to be predisposing factors for the development of sinus disease or operative complications. Thus, it is necessary for the radiologist and surgeon to be cognizant of these variations, especially if the patient is a candidate for FESS.

Variations of the Middle Turbinate

Paradoxic Curvature

Normally, the convexity of the middle turbinate bone is directed medially, toward the nasal septum. When paradoxically curved, the convexity of the bone is directed laterally toward the lateral sinus wall(Fig. 3-16). The inferior edge of the middle turbinate may assume various shapes with exces-

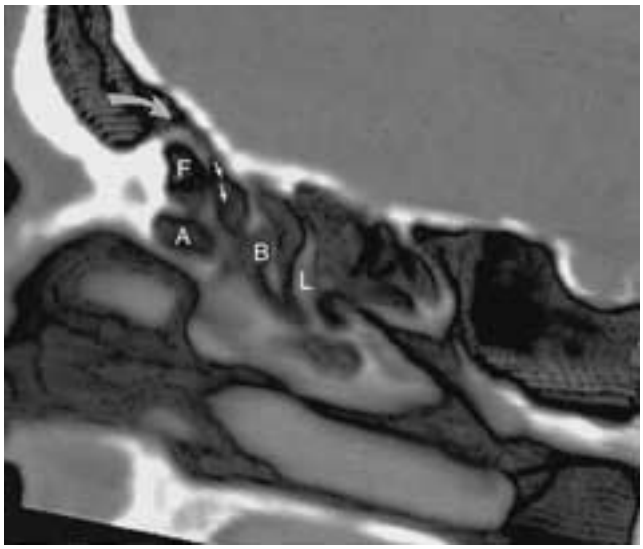

FIGURE 3-7 Saggital 3D image of the frontal recess and adjacent anatomy. This three-dimensional image of the lateral nasal wall reveals the agger nasi cell (*A*) and the frontal cell (*F*). TYPE IV	Single isolated cell within the frontal sinus

sive curvature, which in turn may narrow and/or obstruct the nasal cavity, infundibulum, and middle meatus. Because of this potential narrowing or obstruction, most authors agree that paradoxic middle turbinates can be a contributing factor to sinusitis. Certain authors have, however, found no significant relationship between paradoxically curved middle turbinates and recurrent sinusitis: Lloyd reported no correlation between the variant and increased incidences of asymptomatic sinusitis, and Calhoun et al. found no statistical correlation between paradoxical curvature of the middle turbinate and symptomatic sinusitis.[44, 54]

Concha Bullosa

A concha bullosa is an aerated turbinate, most often the middle turbinate. Although it may be either unilateral or bilateral (Fig. 3-17), Lloyd et al. report it occurring bilaterally more frequently.[55] Less frequently, aeration of the superior turbinate may occur, and an aerated inferior turbinate is uncommon. Concha bullosae are classified according to the degree and portion of turbinate pneumatization. When the pneumatization involves the bulbous segment of the middle turbinate, the term *concha bullosa* applies. If only the attachment portion of the middle turbinate is pneumatized, and the pneumatization does not extend into the bulbous segment, it is known as a lamellar concha.

The reported prevalence of concha bullosa, or pneumatized middle turbinate, varies greatly. Two separate cadaveric studies found concha bullosa in 8% and 20% of specimens, respectively.[51] The reported prevalence of the radiographic appearance of concha bullosa on coronal CT scans ranges from 14% to 53%.[44, 53] The significant discrepancy in the reported prevalence of concha bullosa is due to several possible factors. Attempts to determine the general prevalence of this variation have been characterized by the use of diverse study populations, different criteria for pneumatization, and analytic methods. These varying features have undoubtedly affected the results of the investigations.

Although middle turbinate pneumatization has been suspected as a potential cause of middle meatal obstruction and resultant sinusitis, the definitive relationship between concha bullosa and sinusitis continues to be debated. A concha bullosa involving the middle turbinate may enlarge

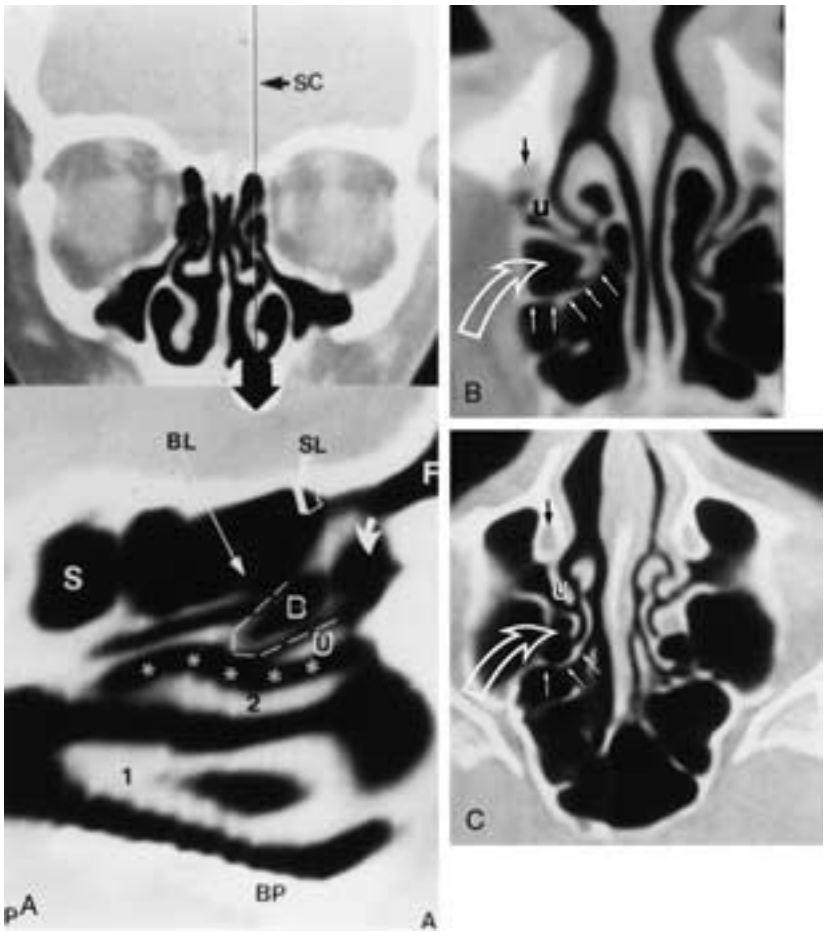
the turbinate, so that it obstructs the middle meatus or the infundibulum, and extensively pneumatized middle turbinates are associated with a higher prevalence of ipsilateral sinus disease.[43, 56] This is especially true when the concha bullosa exists in conjunction with another anatomic configuration that may obstruct the ostiomeatal complex, such as an extensively pneumatized ethmoid bulla.[51]

The air cavity in a concha bullosa is lined with the same epithelium as the rest of the sinonasal cavities. Thus these concha bullosa cells can experience the same inflammatory disorders that affect the paranasal sinuses, and obstruction of the drainage of a concha may also lead to mucocele formation (Fig. 3-18). Isolated or smaller conchae bullosae, or those in which pneumatization is confined to the anterior or inferior aspect of the middle turbinate (farther from the ethmoid infundibulum), are less frequently associated with symptoms of sinusitis.[51]

Other Variations

Additional variations of the middle turbinate can occur, including medial displacement, lateral displacement, lateral bending, L shape, and sagittal transverse clefts (Fig. 3-19). Medial displacement of the middle turbinate is the result of other middle meatal structures (i.e., polypoid disease, pneumatized uncinate process) encroaching upon the middle turbinate. Lateral displacement of the middle turbinate is usually due to the compression of the turbinate toward the lateral nasal wall by a septal spur or septal deviation. Either or these two variants may predispose to sinus disease.[51] L-shaped and lateral bending of the middle turbinate, as well as sagittal or transverse clefting, may also be observed; however, these variants are not associated with sinusitis.[51]



VIEW IMAGE

Nasal Septal Deviation

The nasal septum is fundamental to the development of the nose and paranasal sinuses. Nasal septal deviation is usually congenital but may be posttraumatic in some patients. Malalignment of the components of the adult nasal septum (septal cartilage, perpendicular ethmoidal plate, and vomer) may cause deviation of the nasal septum, deformity of the chondrovomerine articulation, or a septal spur. Asymptomatic septal deviation is observed in 20% to 31% of the population; however, more significant deviation, especially at the level of the chondrovomerine articulation, may contribute to sinusitis symptoms.[46, 48] Severe asymmetric bowing of the nasal septum may compress the middle turbinate laterally, narrowing the middle meatus (Fig. 3-20), and the presence of associated bony spurs may further compromise the OMU. Obstruction, secondary inflammation, swollen membranes, and infection of the middle meatus have all been observed as a result of severe nasal septal deviation.[57]

The dotted lines denote the position of the sagittal planes displayed in **C** and **D**. Frontal sinus (*F*) and maxillary sinus (*M*). **C**, Paraseptal CT image of a cadaver head shows that the sphenoid sinus (*S*) is the most posterior and superior air space and that it is accessible from the posterior ethmoid sinus (*PE*). Frontal sinus (*F*). **D**, Sagittal CT image of a cadaver head performed approximately 1.5 cm lateral to the nasal septum shows that the sphenoid sinus (*S*) is inferior to the posterior ethmoid sinus (*PE*). Frontal sinus (*F*).

Uncinate Process Variations

Deviation

The uncinate process is one of the crucial bony structures of the wall of the lateral nasal cavity. Together with the ethmoid bulla, it forms the boundaries of the hiatus semilunaris and ethmoid infundibulum, the structures through which the frontal and maxillary sinuses drain. The course of the free edge of the uncinate process may be configured in a variety of ways. In most cases, it either extends slightly obliquely toward the nasal septum, with the free edge surrounding the inferoanterior surface of the ethmoid bulla, or it extends more medially to the medial surface of the ethmoid bulla. If the free edge of the uncinate is deviated in a more lateral direction, it may cause narrowing or obstruction of the hiatus semilunaris and infundibulum. Less frequently, a medial deviation or ''curling'' of the uncinate is encountered, which may result in the structure's contact and subsequent obstruction of the middle meatus (Fig. 3-21).

FIGURE 3-15 Relationship between the posterior ethmoid sinus and the sphenoid sinus. Coronal CT image through the middle sphenoid sinus reveals a horizontal bony membranous structure (*solid arrow*). This structure is not a septation; rather, it represents the separation from the sphenoid sinus inferiorly and the posterior ethmoid sinus superiorly. Septations (*open arrow*) are vertically oriented.

ment include attachment to the lamina papyracea, the lateral surface of the middle turbinate, or the fovea ethmoidalis in the floor of the anterior cranial fossa (Fig. 3-22). It is necessary for the surgeon to be cognizant of any of these variations in the patient undergoing FESS, especially when an uncinatectomy is contemplated. In particular, if the uncinate process attaches to the ethmoidal roof or middle turbinate, the surgeon must take special care not to put aggressive traction or torque on the upper tip of the structure during uncinatectomy, as this could inadvertently damage the ethmoid roof and result in CSF rhinorrhea or other intracranial complications.

Sometimes the free edge of the uncinate process adheres to the orbital floor, or inferior aspect of the lamina papyracea. This is referred to as an atelectatic uncinate process (Fig. 3-23) and is associated with a hypoplastic, and often opacified, ipsilateral maxillary sinus due to closure of the infundibulum. For surgical planning, it is important to note this variant, as the ipsilateral orbital floor is low-lying as a result of the hypoplastic maxillary sinus, increasing the risk of inadvertent penetration of the orbit during surgery.

An additional variant of the uncinate process configuration is its extension superiorly to the roof of the anterior ethmoid sinus, causing the superior infundibulum to end as a ''blind pouch.'' This continuation of the uncinate is referred to as the lamina terminalis. In these cases, the infundibulum drains via the posterior aspect of the middle meatus.

Pneumatization

Pneumatization of the uncinate process, also referred to as an uncinate bulla, has been suggested as a predisposing factor for impaired sinus ventilation, especially in the anterior ethmoid, frontal recess, and infundibular regions (Fig. 3-24).[58] Functionally, the pneumatized uncinate process resembles a concha bullosa or an enlarged ethmoid bulla. The pneumatization of the uncinate process is believed to be due to extension of the agger nasi cell within the anterosuperior portion of the uncinate process.[21] The reported incidence of this variant is relatively low, ranging from 0.4% to 2.5% to 18%.[11, 43]

Infraorbital Ethmoid Cells (Haller's Cells)

Infraorbital ethmoid cells are pneumatized ethmoid air cells that project along the medial roof of the maxillary sinus and the most inferior portion of the lamina papyracea, below the ethmoid bulla and lateral to the uncinate process (Fig. 3-25). These cells were first identified by Haller in 1765 and subsequently named after him; recently, however, the preferred term for these air cells has been changed to reflect both a growing trend that discourages the naming of structures after anatomists who first describe them, as well as the need for international standardization and descriptive nomenclature for anatomic terms.[36] Most often, infraorbital

FIGURE 3-17 Concha bullosa in two different patients. **A**, Coronal CT image demonstrates a prominent right concha bullosa (*asterisk*) with communication to the frontal recess (*small arrow*). Note the obstruction of the right middle meatus (*curved arrow*). **B**, Coronal CT image demonstrates a left-sided concha bullosa (*asterisk*) with communication to the sinus lateralis (*small arrow*). Note the contralateral Haller (infraorbital ethmoid) cell (*H*).

ethmoid cells arise from the anterior ethmoid cells and are closely related to the infundibulum.[48] These cells contribute to the narrowing of the infundibulum and may also compromise the adjacent ostium of the maxillary sinuses. Consequently, many authors cite infraorbital ethmoid cells as a factor in recurrent maxillary sinusitis.[57, 58]

Some authors consider the existence of this variant a predisposing factor for recurrent maxillary sinusitis. However, Bolger et al. reported an incidence of 45%, and their study found no statistical difference between the prevalence of infraorbital ethmoid cells in patients presenting with recurrent maxillary sinusitis and asymptomatic patients. This led these investigators to suggest that the role of infraorbital ethmoid cells in disease should be evaluated on an individual basis, depending on the size, placement, and evidence of inflammation in the cell.[43]

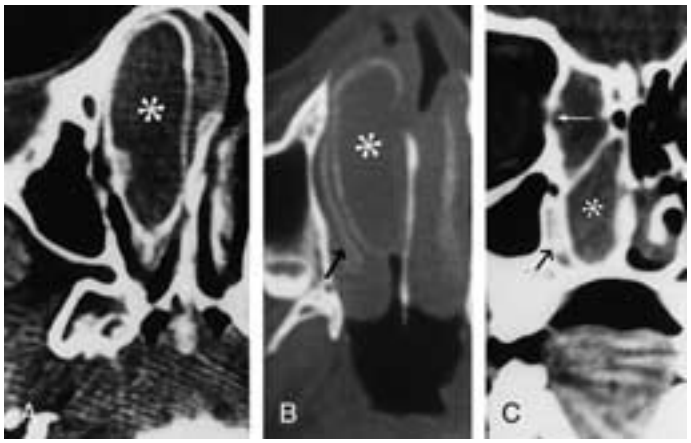

FIGURE 3-18 Mucocele within a concha bullosa. Axial (**A** and **B**) and coronal (**C**) CT images show a prominent soft-tissue mass (*asterisk*) well circumscribed by a bony perimeter (the bony framework of the concha bullosa). The inferior turbinate is compressed against the medial wall of the maxillary sinus (*black arrow*). In the coronal image, the extent of the obstruction of the nasal cavity is apparent, as is the presence of a more superior mucocele, which erodes the lamina papyracea (*white arrow*).

FIGURE 3-19 Coronal CT scans. **A** to **D**, The free edge of the middle turbinate may also assume some other shapes. Note its prominent lateral curvature in this case (*asterisk*). It obstructs the nasal passage (*fine white arrows*) and contributes to the position of the uncinate process and, therefore, the prominent narrowing of the infundibulum (*open arrow*).

Onodi Cells

Two primary definitions of Onodi cells have been presented in the literature. The first defines them as the most posterior ethmoid cells, being superolateral to the sphenoid sinus and closely associated with the optic nerve.[39, 59, 60] Another, more general description defines Onodi cells as posterior ethmoid cells extending into the sphenoid bone, situated either adjacent to or impinging upon the optic nerve.[36] The reported incidence of Onodi cells ranges from 3.4% to 51%.[52] This discrepancy is most likely due to the use of different criteria to define these cells. Onodi cells abut or may even surround the optic nerve, thereby placing this nerve at risk when surgical excision of these cells is performed.

Onodi cells are also a potential cause of incomplete sphenoidectomy. If a surgeon is operating in an Onodi cell, he or she may recognize landmarks traditionally associated with the sphenoid sinus (internal carotid artery, optic nerve) and thus mistakenly conclude that the sphenoid sinus has been entered.

Ethmoid Bulla Variations

The ethmoid bulla is usually the largest and most constant anterior ethmoid air cell. Its appearance varies considerably, based on the extent of pneumatization; extensive pneumatization may obstruct the ostiomeatal complex. Elongated ethmoid bullae are usually the result of pneumatization that extends in a superior to inferior direction rather than in an anterior to posterior direction. Because such pneumatization does not extend in an anterior or posterior direction, elongated ethmoid bullae are relatively unlikely to obstruct the ostiomeatal complex.

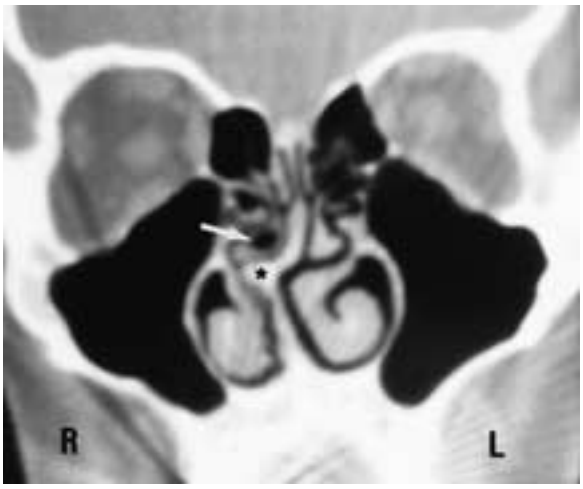

FIGURE 3-20 Nasal septal deviation with spurring. Coronal CT image demonstrates that there is deviation of the nasal septum toward the right side, with a right-sided cartilaginous nasal ''spur'' (*asterisk*). Note the ipsilateral concha bullosa (*arrow*). Both of these anatomic variants contribute to marked narrowing of the right nasal cavity and ethmoid passages.

VIEW IMAGE

Extensive Pneumatization of the Sphenoid Sinus

Although encountered infrequently, pneumatization of the sphenoid sinus that extends into the lesser wing and the anterior and posterior clinoid processes is important to note. A pneumatized anterior clinoid process is associated with Type 2 and Type 3 optic canal configurations (see below), making these nerves especially vulnerable to injury during FESS.[61] A more extensive description of the relationship between the posterior paranasal sinuses and the optic nerves, optic nerve configurations, and their reported incidence can be found in the sections discussing the systematic evaluation of paranasal sinus CT examinations (Fig. 3-26).

Medial Deviation or Dehiscence of the Lamina Papyracea

Medial deviation or dehiscence of the lamina papyracea may be either congenital or the result of prior facial trauma. In either case, if the surgeon does not know about this

FIGURE 3-21 Medially curved uncinate process. **A** and **B**, Coronal CT images through the ethmoid sinuses show a prominent right-sided deviation of the nasal septum (*straight open arrow*). Note the medially curved left uncinate process (*curved open arrow*), which is medially displacing the left middle turbinate (+) and obstructs the left middle meatus. A left-sided Haller (infraorbital ethmoid) cell is present (*small arrow*).

The presence of anterior clinoid pneumatization is an important indicator of optic nerve vulnerability during FESS.

situation preoperatively, the orbital contents are placed at risk during surgery, as the surgeon will not know that there is a restricted ethmoid complex in which to operate (Fig. 3-27). Both excessive medial deviation and bony dehiscence of the lamina papyracea occur most often at the site of the insertion of the basal lamella into the lamina papyracea, thus rendering this portion of the lamina papyracea most delicate.

Aerated Crista Galli

When aeration of the normally bony crista galli occurs, the aerated cells may communicate with the frontal recess, and obstruction of this ostium can lead to chronic sinusitis and mucocele formation within the crista galli. To avoid unnecessary surgical extension into the anterior cranial vault, it is important to recognize an aerated crista galli and differentiate it from an ethmoid air cell prior to surgery.

Cephalocele

Cephaloceles involving the anterior cranial fossa floor may be congenital, occur spontaneously, or be the result of previous ethmoid or sphenoid sinus surgery. Preoperative coronal CT scanning is especially well suited to display the extent of any such areas of missing bone (Figs. 3-28, 3-29) (see also Chapters 1, 4, and 5).[62]

Posterior Nasal Septal Air Cell

Air cells are commonly found within the posterosuperior portion of the nasal septum and, when present, communicate with the sphenoid sinus. As a result, any inflammatory disease that occurs within the paranasal sinuses may also affect these cells (Fig. 3-30). Such disease may opacify this cell, causing it to resemble a cephalocele. CT and MR imaging usually define the involved pathology and resolve any differential diagnostic problems.

Asymmetry in Ethmoid Roof Height

It is important to note any asymmetry in the height of the ethmoid roof, as there is a higher incidence of intracranial penetration during FESS when this anatomic variation occurs. Intracranial penetration is more likely to occur on the side where the position of the roof is lower.[63]

Systematic Radiographic Evaluation

Routine Report

When interpreting sinus CT studies, it is helpful to use a systematic approach. In this regard, most radiologists progress from anterior to posterior when describing findings. As one reads the study, a mental checklist should be made of important structures for evaluation and comment. The reporting system normally includes three steps, which will now be described.

Step One

Identify and describe the important structures of the paranasal sinuses (there are 14 such structures). The dictated report should mention the status of these structures on both the right and left sides. The structures to identify are as follows:

- Frontal sinus
- Frontal recess
- Agger nasi cell and anterior ethmoid sinus
- Maxillary sinus
- Uncinate process
- Infundibulum
- Ethmoid roof
- Ethmoid bulla
- Basal lamella
- Sinus lateralis
- Posterior ethmoid sinus
- Sphenoid sinus
- Middle meatus
- Nasal septum and nasal turbinates

VIEW IMAGE

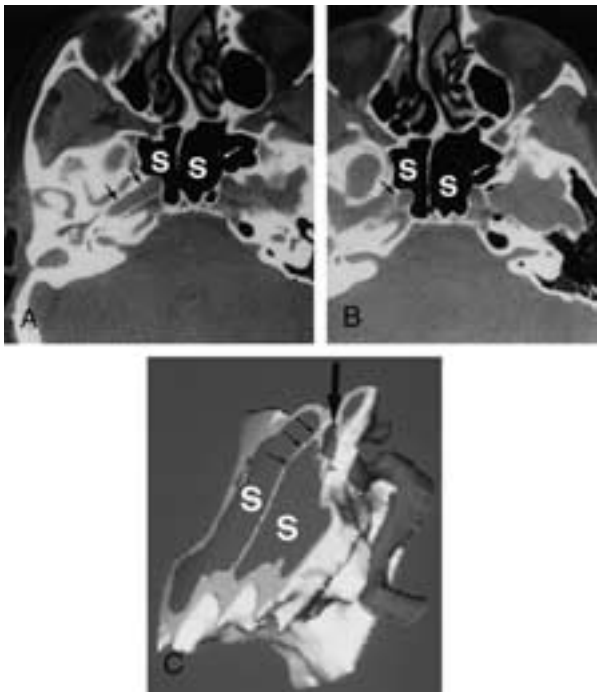
This was proven to be a mucocele within a posterior nasal septal air cell.

Step Two

Evaluate the critical relationships. In addition to describing findings directly related to the diagnosis of inflammatory sinus disease, it is important for the radiologist to evaluate several critical areas that aid in surgical planning. The symmetry of the ethmoid roof should be noted. Careful attention should be paid to the status of the lamina papyracea, and any dehiscence or excessive medial deviation should be reported. The relationship of the sphenoid sinus and posterior ethmoid air cells with the internal carotid artery and optic nerves should be clearly mentioned. In particular, extensive expansion of the sinuses around the internal carotid artery or the optic nerve, as well as bony dehiscences adjacent to either structure, should be noted and reported to the referring surgeon (Fig. 3-31). The incidence of bony dehiscence around the presellar and juxtasellar portions of the internal carotid artery ranges from 12% to 22%.[61, 64, 65]

Frequently the carotid canal extends into the aerated portion of the sphenoid sinus, and in many such cases the sphenoid sinus septations adhere to the bony covering of the carotid canal. The surgeon must be made aware of this situation in order to prevent fracturing of the sphenoid sinus septum/carotid canal junction and puncturing of the carotid artery.

The relationship between the posterior paranasal sinuses and the optic nerves is crucial to note during the radiographic examination (Fig. 3-32). The optic nerves, carotid arteries, and vidian nerves develop prior to the paranasal sinuses, which accounts for their influence on congenital variations in the walls of the sphenoid sinus. Awareness of the intercommunication between the sphenoid sinus, posterior ethmoid cells, and optic nerves is paramount to avoid potentially devastating operative complications during FESS. Delano et al. described four discrete classifications of the various relationships that exist between the optic nerves and posterior paranasal sinuses.[61] Type 1 optic nerves include those that course immediately adjacent to the sphenoid sinus, without indentation of the wall or contact with the posterior ethmoid air cell. This is the most common type, occurring in 76% of patients. Type 2 nerves course adjacent to the sphenoid sinus, causing indentation of the sinus wall, without contact with the posterior ethmoid air cell. Type 3 nerves course through the sphenoid sinus, with at least 50% of the nerve surrounded by air. Type 4 nerves course immediately adjacent to the sphenoid sinus and posterior ethmoid sinus. The optic nerve is exposed without a complete bony margin in all cases where it travels through the sphenoid sinus (Type 3) and in 82% of cases where the nerve is impressed on the sphenoid sinus wall (Type 2).



VIEW IMAGE

FIGURE 3-31 Relationship of the carotid canal to the sphenoid sinus. **A** and **B**, Axial CT images through the sphenoid and ethmoid sinuses show that the carotid canals (*small black arrows*) penetrate into the sphenoid sinus (*S*). An incomplete sphenoid sinus septum (*white arrow*) connects to the bony covering of the carotid canal. **C**, Three-dimensional images of the sphenoid sinus (*S*) and presellar and juxtasellar portions of the internal carotid artery (*black arrow*) graphically display the close relationship between the internal carotid artery and the sphenoid sinus septation (*small black arrows*).

VIEW IMAGE

FIGURE 3-32 Relationship of the optic nerves to the sphenoid sinus. Type 3 optic nerves (*black arrows*) course through the sphenoid sinus, with more than 50% of the nerves surrounded by air. Note that there is dehiscence of the bone covering the right optic nerve (*curved white arrow*). This increases the risk of optic nerve damage during FESS.

Delano et al. also found that 85% of optic nerves associated with a pneumatized anterior clinoid process were of the Type 2 or Type 3 configuration, and 77% were dehiscent. Therefore the presence of anterior clinoid pneumatization is an important indicator of optic nerve vulnerability during FESS because of the frequent association of this pneumatization with both bony dehiscence and Type 2 and 3 optic nerve configurations.[61]

Step Three

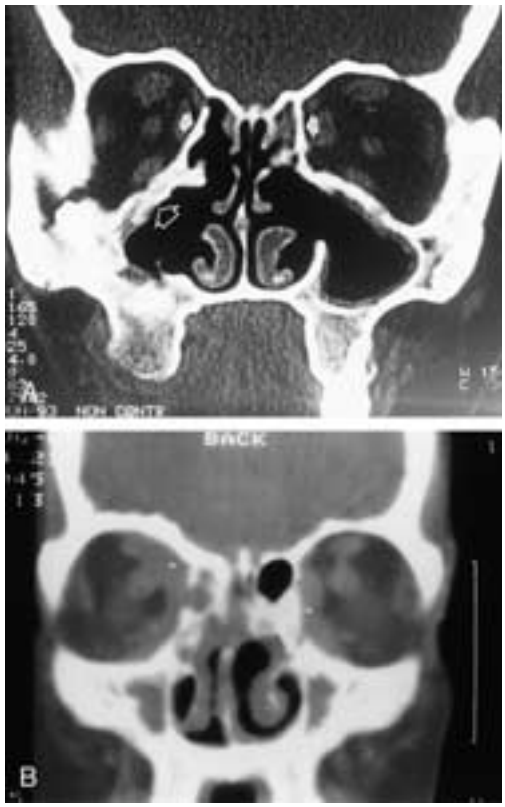
Lastly, but just as important as steps one and two, is the evaluation of the ''character'' of the bony framework of the nasal vault and paranasal sinuses. It has been noted that a prominent thickening of the bone about a paranasal sinus may occur, especially in patients who have had several surgical procedures and in patients with repeated exacerbations of chronic inflammation (Fig. 3-33). Similar changes have been noted in patients with Wegener's granulomatosis and in patients who suffer from a prolonged chronic inflammation and have had no previous surgery. Unfortunately, to date there is no good pathophysiologic explanation of this finding. However, it is believed that this change is directly related to the underlying inflammatory process and periosteal stimulation.

Bone may not be visualized on CT for several reasons. Bone may have been removed during a prior surgical procedure and, therefore, a defect is noted. Evidence of prior surgery should be sought on the CT examination and established through a proper medical history. Bone may not be seen because it is deossified secondary to chronic pressure from a mucocele or because the bone is invaded and destroyed by tumor. The associated mass will suggest the etiology, and MR imaging may afford a distinction between these two processes (see Chapter 6). Lastly, bony dehiscences may be developmental, and in the absence of prior surgery or associated pathology, this diagnostic possibility should be considered.

Radiographic Appearances of Inflammatory Sinus Disease

Acute Sinusitis

Acute sinusitis usually is due to bacterial infection of an obstructed paranasal sinus. The obstruction is often the result of apposition of edematous mucosal surfaces from an antecedent viral upper respiratory tract infection. The edematous mucosa disrupts the normal mucociliary drainage pattern of the sinus, and obstruction of the sinus ostium results. This, in turn, alters the oxygen tension within the obstructed sinus and predisposes the sinus to a bacterial superinfection.[24, 43, 66] Acute sinusitis usually involves only a single sinus, with the ethmoid sinus being the most common location.[57, 66] There is an increased risk of regional



VIEW IMAGE

FIGURE 3-33 Osteitis of the paranasal sinus walls. **A**, Coronal CT image through the ethmoid sinus shows that the patient has had bilateral antrostomies, uncinectomies, and partial anterior ethmoidectomies. Note the pronounced thickening of the orbital floors bilaterally but more severely on the right side (*open arrow*). There is marked thickening of the lamina papyracea bilaterally (*solid arrows*). These changes are occasionally seen in patients who have undergone multiple surgical procedures in this area. **B**, Coronal CT image through the anterior ethmoid sinus in a patient with Wegener's granulomatosis. and intracranial complications, with involvement of the frontal, ethmoid, and sphenoid sinuses.[57] Acute sinusitis is rarely the result of a pure viral infection. A thorough discussion of sinusitis is presented in Chapter 5.

Chronic Sinusitis

Chronic sinusitis is diagnosed when the patient has repeated bouts of acute infection or persistent inflammation.[57, 66] Staphylococcus, streptococcus, corynebacteria, bacteroides, fusobacteria, and other anaerobes and anerobes are more commonly involved in chronic sinusitis than in acute sinusitis.[43, 57, 66] The radiographic findings are quite variable and are discussed in Chapter 5.[67] The sinuses most commonly involved with chronic sinusitis are the anterior ethmoid air cells.

Opacification of the OMU has been found to predispose patients to the development of sinusitis. Zinreich et al. found middle meatus opacification in 72% of patients with chronic sinusitis. In this study, 65% of these patients had mucoperiosteal thickening within the maxillary sinus, and all of the patients with frontal sinusitis had opacification of the frontoethmoidal recess.[6, 8, 9] Opacification of the OMU without frontal, maxillary, or anterior ethmoid sinus inflammatory disease was rare.[6, 8, 9] Yousem et al. found that when the middle meatus was opacified, there were associated inflammatory changes in the ethmoid sinuses in 82% of patients and in the maxillary sinuses in 84% of patients.[68] Bolger et al. found that when the ethmoid infundibulum was free of disease, the maxillary and frontal sinuses were clear in 77% of patients.[43]

Babbel et al. reviewed 500 patients with screening sinus CT scans and defined five recurring patterns of inflammatory sinonasal disease.[69] The five anatomic patterns were infundibular, OMU, sphenoethmoidal recess, sinonasal polyposis, and sporadic or unclassifiable. The infundibular pattern (26% of patients) referred to focal obstruction within the maxillary sinus ostium and ethmoid infundibulum, which was associated with maxillary sinus disease. The OMU pattern (25% of patients) referred to ipsilateral maxillary, frontal, and anterior ethmoid sinus disease (Fig. 3-34). This pattern was due to obstruction of the middle meatus. Sparing of the frontal sinus was sometimes seen as a result of the variable location of the nasofrontal duct insertion in the middle meatus. The sphenoethmoidal recess pattern (6% of patients) resulted in sphenoid or posterior ethmoid sinus inflammation caused by sphenoethmoidal recess obstruction. The sinonasal polyposis pattern (10% of patients) was due to diffuse nasal and paranasal sinus polyps. Associated radiographic findings included infundibular enlargement, convexity (bulging) of the ethmoid sinus walls, and thinning of the bony nasal septum and ethmoid trabeculae.[28, 69, 70]

Certain anatomic variants, as described above, have been implicated as causative factors in the presence of chronic inflammatory disease. Stammberger and Wolf and Lidov and Som found that a large concha bullosa produced signs and symptoms of sinusitis.[58, 71] However, Yousem et al. found that the presence of a concha bullosa did not increase the risk of sinusitis.[68] This was corroborated by Bolger et al., who found that the presence of a concha bullosa, paradoxic turbinates, Haller cells, and uncinate process pneumatization were not significantly more common in patients with chronic sinusitis than in asymptomatic patients.[43] Yousem et al. found that the presence of nasal septal deviation and a horizontally oriented uncinate process was more common in patients with inflammatory sinusitis.[68] Although the presence of these variants may not necessarily predispose to sinusitis, it appears that the size of a given anatomic variant and its relationship to adjacent structures plays an important role in the development of sinusitis.[37]

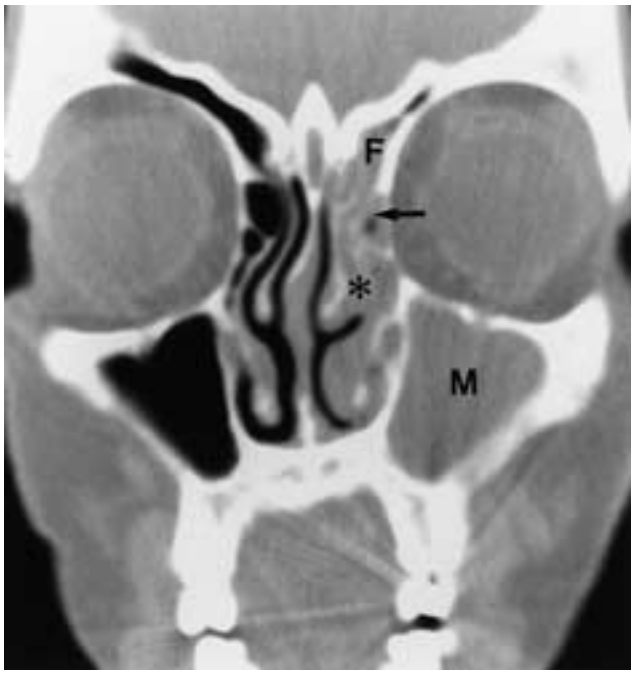

FIGURE 3-34 OMU pattern of sinusitis. Inflammatory changes obstruct the left middle meatus (*asterisk*), with resulting opacification of the left maxillary (*M*), frontal (*F*), and anterior ethmoid (*arrow*) sinuses.

VIEW IMAGE

Fungal Sinusitis

Fungal sinusitis may be suspected clinically when the patient fails to respond to standard antibiotic therapy.[37, 57, 68, 72, 73] According to Som and Curtin, two circumstances can be seen that suggest the presence of fungal infections: soft tissue changes in the sinus associated with thickened, reactive bone with localized areas of osteomyelitis, and the association of inflammatory sinus disease with involvement of the adjacent nasal fossa and the soft tissues of the cheek.[21, 22] These signs of aggressive infection are atypical of bacterial pathogens. This topic is described in detail in Chapter 5.

Allergic Sinusitis

Allergic sinusitis occurs in 10% of the population and typically produces a pansinusitis with symmetric involvement.[28, 69] CT often shows a nodular mucosal thickening with thickened turbinates; air-fluid levels are rare unless bacterial superinfection occurs.[28, 67] This topic is discussed in more detail in Chapter 5.

Orbital Complications of Sinusitis

About 3% of patients with sinusitis have some form of orbital involvement. These complications are more common in children than in adults, and the orbital manifestations may

Copyright © 2003, Mosby, Inc. All rights reserved.

be the initial clinical signs of sinus infection. Complicated sinusitis is the most common cause of orbital infection, accounting for 60% to 84% of cases.[38, 74–77] The origin of the infection most commonly is in the ethmoid sinuses. In decreasing order of frequency, the sources of the infection are the frontal, sphenoid, and maxillary sinuses. The ethmoid and maxillary sinuses are present at birth and therefore are the source in younger children. The topic of orbital infection is discussed in detail in Chapter 9.

COMMON FESS TECHNIQUES

For the surgical treatment of inflammatory sinonasal disease, FESS has largely replaced more traditional sinus surgery techniques. It is now believed that obstruction of the drainage portals of the sinuses, particularly the anterior ethmoids, is the primary cause of recurrent sinusitis. The rationale for FESS is that these techniques allow restoration of the flow of sinus secretions through their native drainage portals, allowing the inflamed sinus to return to a normal state, thus hopefully alleviating the patient's symptoms.[26, 78, 79]

Types of FESS

Panje and Anand have developed a classification system to standardize the type of FESS technique that is appropriate based on the preoperative extent of sinus disease as determined by CT imaging.[79] These authors outline the various types of FESS in the following manner:

Type I

Uncinatectomy with or without agger nasi cell exenteration.

Indications

1. Isolated OMU thickening of mucous membrane
2. Infundibular disease
3. Patent maxillary sinus ostia without maxillary sinus membrane thickening or cysts
4. Unsuccessful prior inferior maxillary sinus antrostomy or antrotomy with irrigation
5. Prior septoplasty or adenoidectomy with continued paranasal sinus symptoms

Type II

Uncinatectomy, bulla ethmoidectomy, removal of the sinus lateralis mucous membrane, and exposure of the frontal recess or frontal sinus.

Indications

1. OMU thickening of the mucous membrane
2. Evidence of anterior ethmoid sinus opacification, including obstruction of the infundibulum
3. Limited frontal recess disease
4. Unsuccessful prior inferior maxillary sinus antrostomy or antrotomy with irrigation
5. Prior septoplasty or adenoidectomy with continued paranasal sinus symptoms

Type III

Type II plus maxillary sinus antrostomy through the natural sinus ostium.

Indications

Same as for Type II, with the following:

1. Maxillary sinusitis, as evidenced by membrane thickening or sinus opacification
2. Stenotic or edematous maxillary sinus ostium

Type IV

Type III plus complete posterior ethmoidectomy.

Indications

Same as for Type III, with the following:

1. Total ethmoid involvement
2. Nasal polyposis with extensive ethmoidal and maxillary sinus disease
3. Prior Type I or Type II FESS without a response or with progression of sinus disease

Type V

Type IV plus sphenoidectomy and stripping of the mucous membrane.

Indications

Same as for Type IV, with the following:

1. Evidence of sphenoid sinusitis
2. Pansinusitis and rhinitis

In practice, Types II and III are the most commonly performed FESS techniques.

RADIOGRAPHIC EVALUATION OF PATIENTS FOLLOWING FUNCTIONAL ENDOSCOPIC SINUS SURGERY

Expected Findings

Evaluation of the postoperative patient is similar to that of the preoperative patient. Ideally, the CT scan should be performed in the coronal projection. Given the fact that a surgical procedure was performed, the type and extent of surgery must be established. Subsequently the emphasis is on the anatomy. The mental checklist should identify and mention the presence or absence of the 14 important structures discussed earlier in this chapter. A close look at the nasal cavity and paranasal sinus boundaries and the important relationships described previously should once again be observed and evaluated. Areas of bony thickening or dehiscence should be noted.

Areas that merit close scrutiny on follow-up (postoperative) CT scans are as follows:

1. *Frontal recess*. The frontal recess should be identified to determine its patency. Postoperatively, one often finds that recurrence of disease is due to persistent obstruction in this area. It is the narrowest channel within the anterior ethmoid complex, and it is a structure that is very difficult to access surgically. Therefore, the frontal recess is the area most likely to be affected by inflammatory disease in a patient with a previous paranasal sinus surgical procedure. To this

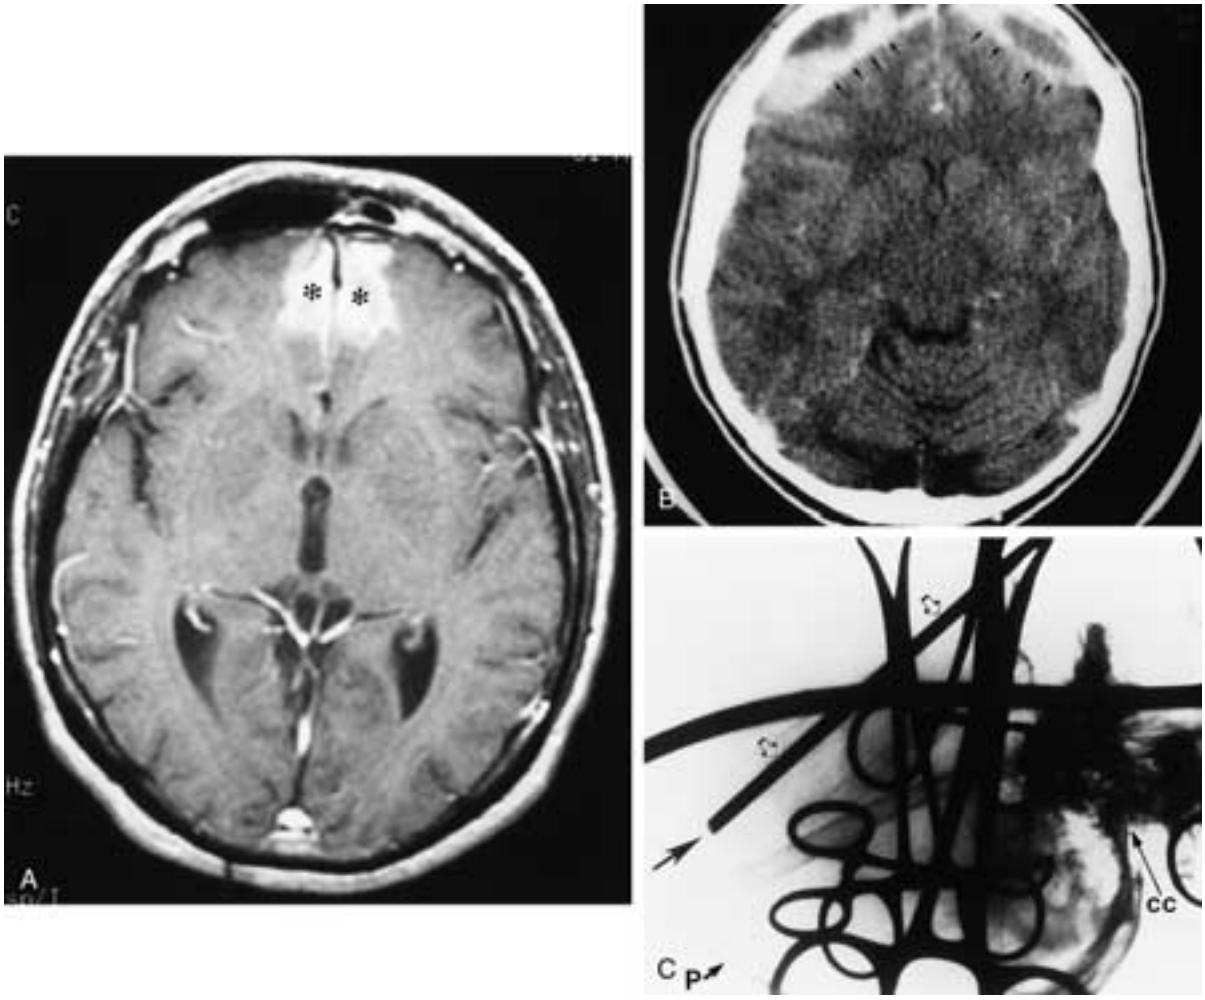
FIGURE 3-35 Anatomic landmarks to be evaluated in patients after FESS. **A**, Coronal CT image through the anterior ethmoid sinuses shows a prominent asymmetry in the position of the roof of the ethmoid sinuses (*solid arrowheads*). The intracranial penetrations (*fine black arrow*) are usually on the side where the roof is lower in position. **B**, Coronal CT image through the anterior ethmoid sinus in a patient after bilateral uncinatectomies and partial middle turbinectomies (*fine white arrows*). If there is an intraorbital complication during such a surgical procedure, it usually involves the lamina papyracea at the attachment of the basal lamella (*curved arrow*).



VIEW IMAGE

FIGURE 3-36 Intracranial complications from FESS. **A**, Axial T1-weighted MR image after gadolinium-DTPA administration shows abnormal bifrontal parenchymal enhancement (*asterisks*) caused by encephalitis from perforation through the cribriform plate. **B**, Axial CT image shows bilateral acute subdural hematomas (*arrows*) after FESS. **C**, Intraoperative cross-table lateral skull radiograph shows the intracranial extension of an endoscope (*open arrows*). Note the position of the endoscope in the deep portion of the posterior frontal lobe (*solid black arrow*). Overlying surgical instruments are noted. Craniocervical junction (*CC*) and parietal bone (*P*).

Copyright © 2003, Mosby, Inc. All rights reserved.

end, note should be made of the agger nasi cell (if it remains), because its persistence may continue to narrow the frontal recess.

2. *OMU*. Note should be made of the extent of the uncinatectomy and removal of the ethmoid bulla. The course of the infundibulum should be examined for persistent anatomic narrowing. The outline of the middle turbinate should be examined to determine whether a middle turbinectomy has been performed. If so, then careful attention should be paid to both the vertical attachment of the middle turbinate to the cribriform plate and the attachment of the basal lamella to the lamina papyracea. Traction applied on the vertical attachment and basal lamella of the middle turbinate during the course of a middle turbinectomy can cause a fracture of the lamina papyracea or the cribriform plate. These breaks in the continuity of the lamina papyracea and ethmoid roof are easily demonstrated on coronal images (Figs. 3-35, 3-36).
3. *Lamina papyracea*. Inspection of the entire course of the lamina papyracea should be carried out to evaluate the integrity of this structure. Postoperative dehiscences are commonly found just posterior to the nasolacrimal duct, and these may be caused by the uncinate resection (Figs. 3-13, 3-35).
4. *Ethmoid roof*. Asymmetry in the position of the roof (fovea ethmoidalis) of the ethmoid sinuses should be noted. Intracranial penetrations usually occur on the side where the position of the roof is lower. One should examine for a break in the continuity of this roof (Fig. 3-35).[63]
5. *Sphenoid sinus area*. The margins of the sphenoid sinus should be evaluated for bony dehiscence or cephalocele.

Operative Complications

The topic of operative complications is discussed in Chapter 4.

  - Overview of the FESS Procedure
  - Postoperative Findings: Expected and Complications

SURGICAL COMPLICATIONS

Major and Minor

The paranasal sinuses are flanked on all sides by important structures. Thus, only the delicate lamina papyracea separates the ethmoid complex from the orbit, the roof of the ethmoids (fovea ethmoidalis) separates these cells from the anterior cranial fossa, the fenestrated cribriform plate separates the roof of the nasal cavity from the anterior cranial fossa, a thin bony carotid canal may separate the cavernous internal carotid artery from the mucosa of the sphenoid sinus, and the optic canal may be surrounded by the sphenoid sinus when there is a pneumatized anterior clinoid process. In addition, glistening, moist, diseased mucosa may look identical to periorbita or even dehiscent, inflamed meninges. As a result of this compact anatomy, when performing functional endoscopic sinus surgery (FESS), it is the endoscopist's experience and anatomic knowledge of the many potential structural variations that may occur in this region that help avoid surgical catastrophes.[1–3]

Preoperative sinus computed tomography (CT) is essential to understand the individual's anatomy and thereby avoid intraoperative complications. However, ultimately, most surgical complications from the endoscopic approach are probably sporadic and are not specifically the result of variant anatomy. Nonetheless, the standard of care is that anatomic variants believed to predispose to surgical complications should be mentioned by the radiologist in the preoperative CT interpretation (see Chapter 3).[4]

Surgical complications can be divided into major and minor events. Complications that require further surgical intervention, or blood transfusion, or that result in a new patient deficit or death, are considered major and include cerebrospinal fluid (CSF) leak, optic nerve injury, ocular motility deficits, injury to the nasolacrimal duct, permanent anosmia, and major intraoperative or perioperative hemorrhage. The incidence of major complications ranges from 0.5% to 9% and the complication rate increases with an inexperienced surgeon, severity of disease (extensive polyposis can hinder the surgeon's visibility), the extensive nature of the surgery, prior FESS, and unusual anatomic variants.[5–9]

Minor complications include periorbital swelling or orbital emphysema, small orbital hematomas, temporary olfactory dysfunction, bleeding that does not require reoperation or blood transfusion (minor epistaxis), and tooth pain. Synechiae and scar formation associated with recurrent symptoms following surgery are reported to occur in 4% to 8% of cases. Usually, the synechiae develop between the lateral nasal wall and the lateral aspect of the middle turbinate, in which case there will be a lateral deviation of the nasal septum. Formation of synechiae in this area can cause middle meatal stenosis and inadequate sinus drainage. Synechiae may also occur between the inferior turbinate and the nasal septum or within the frontal recess.

Approximately 18% of patients reportedly develop recurrent inflammatory disease after a FESS procedure. Although this is not considered a true complication, such recurrent disease is usually mentioned along with the other complications of FESS. The recurrent inflammatory disease

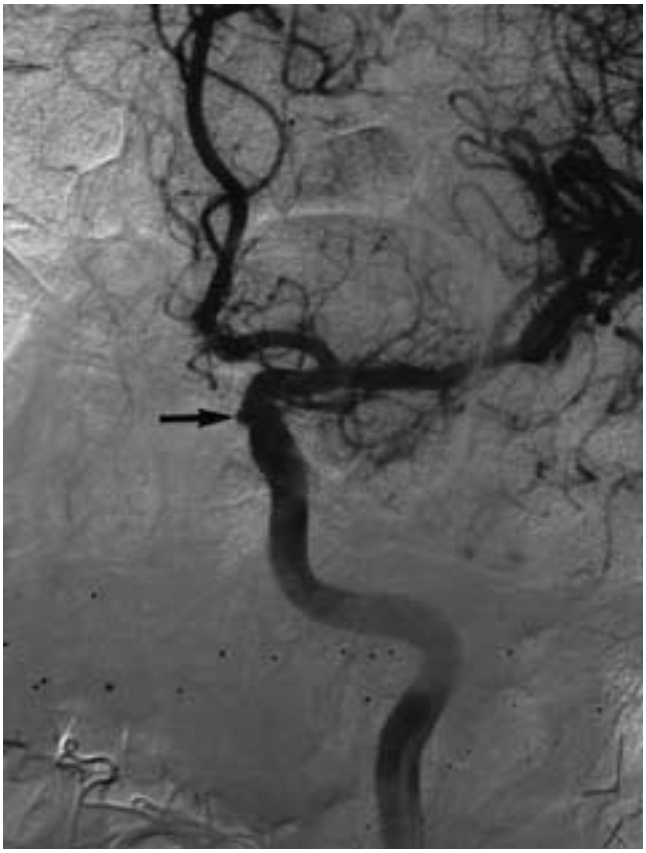
Copyright © 2003, Mosby, Inc. All rights reserved.

may be present because sinusitis is a complex disease that cannot be completely cured by surgery or because the recurrent disease reflects incomplete FESS that did not fully address the ostiomeatal obstruction. Failed FESS is probably underreported, and its exact incidence is not known.

Hemorrhage and Vascular Injury

Hemorrhage requiring transfusion or postoperative packing is a major complication and fortunately is unusual. Extensive disease, especially polyposis, prior FESS, and chronic steroid or aspirin use are risk factors for significant hemorrhage. Bleeding from the internal maxillary artery branches is likely if the turbinates or nasal septum are involved, and injury to the sphenopalatine, anterior, and posterior ethmoidal arteries is the most common reason for hemorrhage.[1]

Posterior bleeding may result from injury to the sphenopalatine artery at the anterior wall of the sphenoid sinus.[10] Injury to the internal carotid artery (ICA) is the most devastating and, fortunately, the rarest complication.[7, 8, 11] (Fig. 4-1). The ICA is vulnerable when surgery is performed in or around the posterior ethmoid air cells and the sphenoid sinus, as absence of the bony carotid wall in the posterior ethmoid or sphenoid sinus is not uncommon. An autopsy series found 71% of ICAs bulging into the sphenoid sinus, with bone only microns in thickness protecting the carotid artery in many cases.[12] In a large CT series, 31.4% of patients had at least one ICA at risk, with extremely thin, bony wall seen on CT about the ICA in 17% of patients and no bony covering found in 14.4%.[13] On the traditional CT window settings used for preoperative sinus imaging, and without intravenous contrast, at times only an estimate of the ICA location can be made. When there is extensive superolateral pneumatization of the posterior ethmoid cell, termed the *Onodi cell*, the ICA and optic nerve may bulge into the pneumatized cell. Pneumatization of the anterior clinoids should be noted, as both the optic nerve and the ICA are theoretically placed at risk. Finally, intrasphenoidal bony sinus septums that insert on or near the carotid canal should be described in the radiology report. Although these septums are variable, they usually arise from the posterior or posterolateral sphenoid sinus wall and are attached at the level of the ICA. If there is a surgical attempt to resect such a septum, the twisting and applied torque may fracture the bone at the level of the ICA and inadvertently injure the vessel.[4] In summary, the ICA is vulnerable during FESS at the lateral wall of the sphenoid sinus if there is a bony septum abutting the lateral wall near the ICA canal, if Onodi cells are present, and if there is a pneumatized anterior clinoid process.



VIEW IMAGE

FIGURE 4-1 Intraoperative hemorrhage during posterior ethmoidectomy. Conventional angiogram, lateral view of a left ICA injection, obtained several hours after massive intraoperative hemorrhage, shows a small pseudoaneurysm (*arrow*) of the left ICA. The patient underwent a test balloon occlusion, developed no neurologic deficits, and had permanent balloon occlusion.

If intraoperative bleeding cannot be stopped with packing, immediate diagnostic conventional angiography is indicated. Perforation or pseudoaneurysm of the cavernous ICA can be assessed on diagnostic angiography, followed by transvascular treatment by the interventional neuroradiologist with endovascular balloon occlusion or coiling of the injured ICA. Temporary balloon occlusion is usually performed initially to determine whether there is an intact circle of Willis that will permit the patient to tolerate sacrifice of the ICA.

Skull Base Injury, Including CSF Leak

Anterior skull base injury results in pneumocephalus, subdural hematoma, intracranial hemorrhage or contusion, cerebritis, or an abcess. There also may be focal encephalomalacia of the gyrus rectus when there has been perforation of the cribriform plate. Factors associated with such injury include dehiscence of the cribriform plate, ethmoid roof, or sphenoid roof (Fig. 4-2). CSF fistula occurs rarely in FESS, but FESS is one of the most common causes of CSF leak.[14] Subsequent development of meningitis or intracranial abscess is unusual, as the defect is generally detected intraoperatively by the surgeon and repaired immediately.[14, 15]

The roof of the ethmoid air cells may be unusually low on one side, potentially placing this ethmoid complex at risk for inadvertent surgical penetration of the anterior cranial fossa. Any asymmetry (especially if marked) in the height of the ethmoid roof on either side should also be noted in the radiology report. Any thinning or dehiscence of the ethmoid roof, cribriform plates, or roof of the sphenoid sinus (whether posttraumatic, congenital, or from prior surgery) is important preoperative information for the surgeon. Therefore, the position, symmetry, and integrity of the roof of the ethmoids, cribriform plate, and planum sphenoidale are always assessed by the radiologist prior to FESS to help avoid a surgical complication (also see Chapter 3). This is

VIEW IMAGE

FIGURE 4-2 Anterior skull base defect with pneumocephalus. The patient presented with headaches immediately following FESS. A CT scan was obtained several days after FESS, revealing pneumocephalus and an anterior skull base defect. **A**, Axial CT scan shows massive intracranial air, including intraventricular air. This implies that the surgical instruments went through the bony anterior skull base. **B**, Direct coronal CT scan shows resection of the entire left middle turbinate, cribriform plate (*arrow*), and roof of the ethmoids (*arrowhead*).

especially important for revision FESS, as previous FESS remains the single most important risk factor for iatrogenic CSF leak.[14]

The anterior vertical insertion of the middle turbinate lies along the lateral edge of the cribriform plate. It is an important surgical landmark, as medial to it is the cribriform plate and lateral lies the roof of the ethmoids. The anterior ethmoid artery (AEA) enters the olfactory fossa at this location, making the lateral cribriform plate, or lateral lamella of the olfactory groove, the thinnest portion and the area most ''exposed'' to perforation.[2] Thus, during FESS, the endoscope must remain lateral to the vertical insertion of the middle turbinate. The olfactory nerve fibers pass through the cribriform plate, and surgical injury to the olfactory mucosa or torque applied to the middle turbinate may injure these fibers as well as create a CSF leak.[3] If the entire vertical insertion of the middle turbinate has been partially or completely resected during prior surgery, it should be noted that an important surgical landmark is missing. Disturbance of olfactory function occurs in about 20% of the patients who have a CSF leak or an anterior skull base defect as a result of FESS.[16]

The posterior ethmoid roof at the border between the posterior ethmoids and sphenoid sinus is an underrecognized location of CSF leak.[1] This area should be scrutinized by the radiologist, especially prior to revision FESS. The posterior ethmoid roof is especially vulnerable to injury because it may be inadvertently misinterpreted during FESS as the anterior aspect of the sphenoid sinus.

When postoperative CSF rhinorrhea is suspected, the nasal secretions should be tested to confirm that CSF is present. Although the glucose-oxidase test was formerly used for this purpose, its high incidence of false-positive results led to the use of the β2-transferrin test. This test is highly sensitive and capable of detecting CSF in only a few millimeters of nasal secretions. If the β2-transferrin test is positive, imaging examinations are indicated.[15, 16]

For the diagnosis and localization of CSF leak following FESS, the literature does not express a definitive bias toward the use of either MR cisternography, high-resolution CT, or CT cisternography. Each has distinct advantages and disadvantages. MR and CT cisternography can identify the actual site of CSF leakage within the nasal cavity or paranasal sinuses, provided that there is an active CSF leak. The MR study, however, does not provide adequate bony detail. Plain high-resolution CT does provide a detailed display of the bone at the site of the leak; however, it does not show the flow of CSF into the sinus. In difficult cases, it is recommended that both techniques be utilized for accurate diagnosis or that a CT cisternogram study be performed. However, since the radiation dose that results from high-resolution CT is significant, MR cisternography is usually the first technique employed. The reported sensitivity of MR cisternography in the diagnosis of CSF fistulae ranges from 87% to 100%. If this examination does not provide adequate information, then high-resolution CT may be utilized. The sensitivity of high-resolution CT reportedly ranges from 71% to 92%. However, in some cases these results may be misleading, as congenital or other bony abnormalities seen may not be associated with the CSF leak.

In many institutions, a radionuclide CSF study is utilized as the initial radiologic screening examination for patients with suspected CSF leaks. Before beginning the study, the otolaryngologist places absorbent pledgets in the nasal cavity. Usually, three to four are placed on each side, and note is made of their location within the nasal cavity. Next, 400 to 500 Ci of ^{111}Indium-labeled (^{111}In) DTPA is placed in the subarachnoid space by the radiologist via a cervical or lum-

Copyright © 2003, Mosby, Inc. All rights reserved.

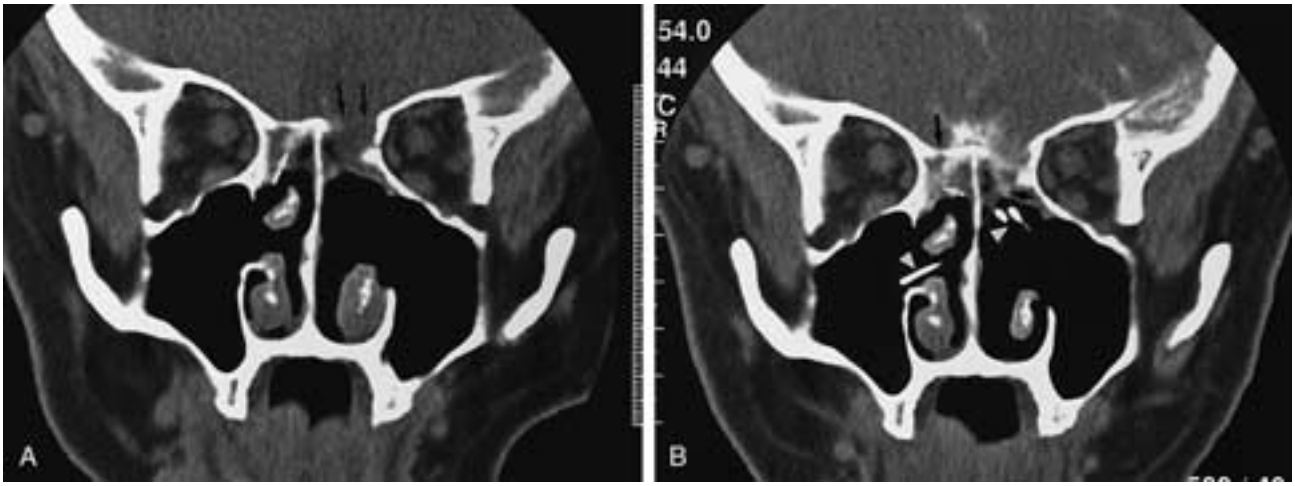
bar puncture. The patient is imaged with a gamma camera at multiple intervals for up to 24 hours. Any position or activity known to provoke the leak is encouraged. Even if the images of the head and neck do not show evidence of a leak, indirect scanning evidence may confirm the presence of a leak by showing activity in the bowel. Such activity indicates that the patient is swallowing CSF as it leaks into the nasal cavity. At 24 hours, the nasal pledgets are removed and assayed. The results are compared with ^{111}In activity in a serum sample drawn at the same time. A ratio of pledget activity to serum activity is determined and expressed in terms of counts per gram. Pledgets showing activity 1.5 times greater than serum activity are considered positive. It is then possible to predict the general area of the leak based on which pledgets show increased activity. Even if none of the pledgets have increased activity, if there is increased activity over the abdomen the radionuclide test is considered positive.

The radiographic evaluation for CSF leak necessitates careful attention to technique and detail. On coronal CT imaging, CSF leak is suspected when there is a bony defect and a fluid level at the site of the defect. These two findings in the setting of a clinically suspected CSF leak strongly predict the presence of a leak. Because the defect may be only millimeters in size, thin-section CT in multiple planes is essential for small defects.

CT cisternography is useful to confirm the leak and can be performed on an outpatient basis. The study begins with a noncontrast thin-section 3-mm coronal CT scan of the sinuses and anterior skull base in the prone coronal position. In the axial plane, 5-mm-thick sections may be adequate. If there is a single bony defect, with or without sinus opacification, in conjunction with a strong clinical history, no further imaging is needed to direct the surgical repair. If no bony defect is seen, the level of clinical suspicion determines whether further imaging is necessary. If the clinical suspicion of a leak is low, the study is deemed normal.

However, if the clinical suspicion of a leak is high, cisternography with intrathecal contrast can be performed. Usually, about 5 ml of nonionic contrast material is placed in the lumbar subarachnoid space, the fluoroscopy table is tilted head down for 1 to 2 minutes, and cranial flow of contrast is confirmed using fluoroscopy. Any maneuvers that provoke CSF rhinorrhea, such as a Valsalva maneuver, should be performed by the patient prior to rescanning. CT scans in the prone coronal and supine axial planes are then repeated. Visualization of contrast within a bony defect or contrast material within a sinus, air cell, or nasal cavity indicates a leak (Fig. 4-3). In subtle cases, there may be no visual suggestion of contrast accumulation, but region of interest (ROI) measurements in a sinus may be increased compared to ROI measurements obtained on the precisternogram CT. Sinus wall sclerosis or osteitis is seen commonly in patients with failed FESS, and the sclerosis might be misinterpreted as contrast extravasation if the precisternogram scan is not carefully compared to the postcontrast scan (Fig. 4-4). Images are best viewed magnified on a workstation, with varied window and level settings to improve detection of contrast accumulation.

Nuclear medicine cisternography can be performed at the same time as CT cisternography. It is especially helpful if the leak is questionable or subtle or if bilateral defects are seen and the site of the leak is not clear.



VIEW IMAGE

FIGURE 4-3 Persistent nasal discharge months after FESS. **A**, Precisternogram coronal CT scan, 3-mm slice thickness, intermediate window, shows obvious bony dehiscence at the posterior ethmoid roof on the left (*black arrows*). Postoperative findings include a thinned, straightened septum from prior septoplasty, widening of each maxillary sinus infundibulum including bilateral uncinectomies, complete resection of the left middle turbinate, and bilateral ethmoidectomies. There is high density within the right complex (*white arrow*), probably from osteitis. This bony sclerosis is often seen in chronic sinus inflammatory disease, especially following FESS. **B**, Postcisternogram coronal CT scan shows high-density nonionic contrast within the subarachnoid spaces. There is a collection of contrast within the soft tissue filling the left posterior ethmoid (*black arrow*) at the location of the bony dehiscence. Subtle contrast accumulation is also seen in the right ethmoid complex (*white arrow*) inferior to the osteitis. The smaller bony defect on the right (*long black arrow*) was not seen on the precisternogram portion of the study. Nasal pledgets, placed for the nuclear cisternogram, are seen bilaterally (*arrowheads*). These were removed at 24 hours to detect the presence of radiopharmaceutical. This additional portion of the study confirms the presence of a leak and is helpful in subtle cases. Also note that the window and level settings (window—500, level—40) are narrower than those used for screening sinus CT. The narrower settings improve visualization of contrast.

VIEW IMAGE

FIGURE 4-4 CSF rhinorrhea months following FESS. This precisternogram coronal CT scan shows the need for precontrast imaging. There is definite osteitis within the right posterior ethmoid complex, but the bony dehiscence is on the left. If only a postcisternogram CT scan had been obtained, the high density on the right might be misinterpreted as contrast accumulation, implying a right-sided leak.

Most iatrogenic skull base defects are detected intraoperatively at the time of injury, and 90% are successfully repaired during the FESS procedure at the first attempt.[14–16] A leak is suspected when there is pooling of clear fluid at the surgical site. A low dose of intrathecal fluorescein placed during or just prior to surgery, with subsequent visualization of the fluorescein at the suspected defect intraoperatively, confirms the leak.[17] A free patch repair involving fascia, mucoperiosteum from the turbinate or nasal septum, free fat, muscle, or fibrin glue may be used.[15] Endoscopic repair of CSF leak is the procedure of choice, with craniotomy reserved for the largest or most complicated defects.

CSF fluid leak, meningitis, or even meningoencephalocele, complications that are associated with FESS, present clinically days to years after surgery.[11, 18] Nonspecific symptoms of nasal obstruction, nasal discharge, or headaches may suggest recurrent sinus inflammatory disease; meningitis is rarely the presenting event. Because the symptoms of CSF leak and recurrent inflammatory disease are similar, careful radiographic assessment of the skull base is especially important in the patient with suspected FESS failure.

The rhinologist will suspect a skull base defect if there is pooling of clear fluid in the nasal cavity or if a frank intranasal mass is detected at nasal endoscopy. Cross-sectional imaging is essential to confirm the bony defect or leak (Fig. 4-2B), characterize the size and pinpoint the location of the bony defect, and determine if there is downward herniation of meninges or brain. The radiologic workup is complex, requiring more than one imaging procedure in subtle defects and MR imaging in large defects when pseudomeningocele (Fig. 4-5) or meningoencephalocele (Fig. 4-6) is suspected. A screening sinus CT scan alone is rarely enough to confirm and precisely characterize the defect.

Computer programs for intraoperative surgical guidance, now widely available, are useful in the workup of a CSF leak. These systems require preoperative CT imaging using a vendor-specific technique, which always includes extremely thin slice increments to allow high spatial resolution, multiplanar reformation capability. The CT data are loaded onto a computer system in the operating room, the data are registered to the patient using fixed fiducial markers, and the location of intranasal instruments is confirmed on the CT image by a system using either optical or electromagnetic detectors. When a CSF leak is strongly suspected, the surgeon may anticipate the need for CT surgical guidance, and the cisternogram can be performed using the required parameters. Thus, extremely thin axial CT sections, with multiplanar reformation capability, are used both for the diagnosis of a bony defect and for surgical guidance.[19] When a leak is detected, the multiplanar reformations allow precise defect localization and accurate measurement of both the depth and the width of the defect. In this regard, the thinner slices improve CSF leak detection.

When a soft-tissue mass is seen within the sinus, especially if it abuts the skull base, herniation of intracranial contents should be suspected. Meninges, CSF, or even the anteroinferior aspect of the frontal lobe can herniate downward through a skull base defect. MR imaging, including postgadolinium-enhanced images, is recommended to characterize the soft tissue within the sinus.[11]

Orbital Complications

Orbital complications are also considered mild or severe and can be secondary to trauma to the nasolacrimal duct, inadvertent penetration of the lamina papyracea, or direct injury to the optic nerve.

Epiphora, or tearing due to interruption of the nasolacrimal duct, and dacryocystitis can result from injury to the duct. Fortunately, most ductal injuries heal spontaneously or remit by spontaneous fistularization into the middle meatus. However, stenosis or total occlusion of the nasolacrimal duct can result from more severe injury. The injury can occur during anterior enlargement of the infundibulum, usually when a backbiter is used to resect the uncinate process, enlarging the communication between the infundibulum and the middle meatus. Injury can also occur distally when an anterior maxillary antrostomy is performed near the inferior meatus.[20] In experienced surgical hands, the reported incidence of post–middle meatal antrostomy epiphora due to nasolacrimal duct injury is between 0.3% and 0.7%. Cross-sectional CT imaging can be used to assess the duct but is not commonly requested, as the duct can be directly explored by the surgeon.[21] Dacryocystography is another method used to assess the lumen of the nasolacrimal duct (see Chapter 10). Ductal dilatation with balloon dacryocystoplasty may be performed or a surgical dacryocystoplasty may be performed to restore the patency of the stenosed ductal segment.[21]

Predisposing anatomic features and variations in both major and minor orbital complications include unnoticed lamina papyracea dehiscences, medially deviated segments of the lamina papyracea (usually above or below the insertion of the basal lamella), prominent deviation of the nasal septum and large concha bullosa (which cause additional spatial limitations during the FESS ethmoidectomy procedure), and an uncinate process that adheres to the

FIGURE 4-6 Postoperative meningoencephalocele, left. Nasal obstruction and persistent rhinorrhea was noted 6 months following FESS. **A**, On this T1-weighted sagittal MR image, note the defect in the anterior skull base (*black arrows*) and the complex large soft-tissue mass in the nasal cavity. The anterior portion of the mass abuts the inferior turbinate (*white arrow*). Inferior turbinate denoted by *T*. **B**, T2-weighted coronal MR image confirms that the mass is primarily fluid inferiorly, but there is intranasal herniation of the frontal lobe. The intact ethmoid roof on the right is denoted by the arrow. **C**, T2-weighted coronal MR image posterior to **B** shows that this portion of the meningoencephalocele is primarily brain tissue. Note the widened maxillary ostium and infundibulum on the left (*arrows*) following surgery and uncinectomy and resection of the left middle turbinate. No surgery had been performed on the right side.

inferior lateral orbit under the ethmoid bulla (atelectatic uncinate process).

When the lamina papyracea has been violated, mild complications may be periorbital ecchymosis, orbital emphysema, or a small orbital hematoma. For these minor injuries, treatment includes close observation for development of proptosis, orbital massage to decrease the intraocular pressure, and antibiotic treatment to prevent development of infection. Imaging is rarely required for these mild orbital FESS complications.

More severe orbital complications from medial orbital wall injury include a large orbital hematoma, edema and swelling of the orbital soft tissues, orbital abscess, injury to the superior or medial rectus muscle (Fig. 4-7), and injury to the optic nerve. The resulting symptoms include orbital pain, proptosis, diplopia, and vision loss.

Orbital hematoma occurs due to either rupture of the orbital ciliary veins or direct injury to the ethmoidal arteries.[21, 22] At the superior aspect of the lamina papyracea, near the level of the superior oblique and medial rectus muscles, the AEA runs within the anterior ethmoidal canal (AEC) and perforates the bony ethmoid wall (Fig. 4-8).[23] It is here that the vessel is most vulnerable. The AEC is often seen on screening sinus CT scans, especially if there is extensive pneumatization of supraorbital air cells. It may have a very thin or dehiscent bony canal, running exposed within the superior ethmoid complex (Fig. 4-9).[22] If the AEA is transected, it may retract into the orbit, the surgeon

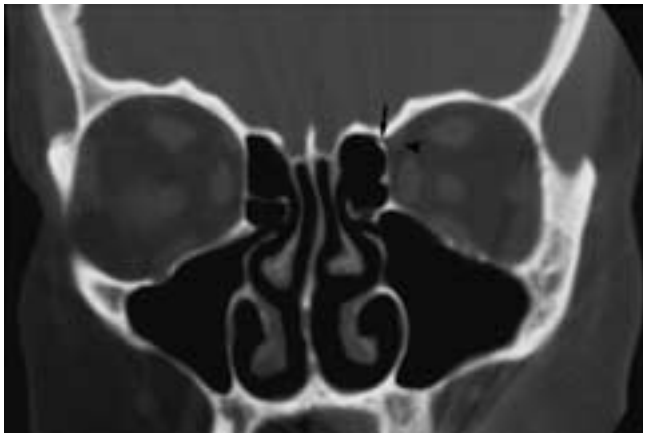
FIGURE 4-7 Diplopia noted immediately after FESS. On this noncontrast axial CT scan, note the small bony fragment, from the lamina papyracea, within the medial rectus muscle on the right (*arrow*).

will lose control of the artery, and an orbital hematoma will result.

Less often there can be injury to the posterior ethmoidal artery, which runs through the posterior ethmoidal foramen approximately 10 to 12 mm posterior to the anterior ethmoidal foramen. Injury to the posterior ethmoidal artery can also cause intraorbital hematoma. However, this artery is relatively close to the optic nerve, and due to this proximity, even small posterior ethmoidal hematomas can cause serious nerve damage, with resultant blindness.

The anterior lamina papyracea may be violated during uncinectomy or surgery of the agger nasi cell. Additionally, incidental lamina papyracea dehiscence, either from prior surgery (Fig. 4-10) or from a previous fracture, likely predisposes to orbital injury during FESS. Congenital



VIEW IMAGE

dehiscence of the lamina papyracea is rare but should be noted on a preoperative sinus CT report (Fig. 4-11).[24] Periorbital fat prolapsing through the defect into the ethmoid complex may be misinterpreted by the surgeon as hypertrophied or diseased mucosa or polypoid disease, and the forceps may tear the fat or injure the extraocular muscles.

Maxillary or ethmoid sinus hypoplasia and a laterally displaced uncinate process also predispose to orbital trauma during FESS. Normally, the medial wall of the orbit is in the same vertical plane as the maxillary ostium.[25] With ethmoid

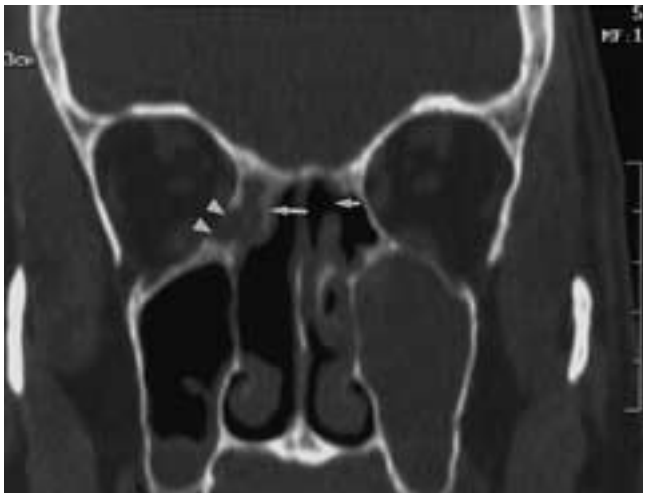

FIGURE 4-10 Recurrent sinusitis and lamina papyracea dehiscence on the right. Axial CT scan data were acquired at 1-mm slice thickness, and this coronal reformatting was performed. There has been a prior septoplasty, ethmoidectomy bilaterally, resection of the inferior portion of the right middle turbinate with a residual superior portion (*long arrow*), and resection of the insertion of the left middle turbinate (*short arrow*), and there is recurrent mucosal thickening in the right maxillary antrum and opacification of the right ethmoid and left maxillary sinuses. Note the lamina papyracea dehiscence on the right (*arrowheads*), increasing the potential risk of orbital injury during revision FESS.

FIGURE 4-12 Maxillary sinus hypoplasia. Coronal diagram of the sinonasal cavity at the level of the osteomeatal unit. On the normal right side, the maxillary sinus opens into the infundibulum through the internal ostium (*arrow*). Note that the ostium is in the same vertical plane as the lamina papyracea. If the maxillary sinus is hypoplastic, as on the left, the medial antral wall is located laterally and the ostium (*arrowhead*) is lateral to the lamina papyracea. This variant predisposes to orbital penetration.

hypoplasia, the medial orbital wall is medial to the vertical plane of the maxillary ostium, presumably predisposing to orbital penetration during FESS.[4, 26] A similar anatomic relationship exists when there is a hypoplastic maxillary sinus; the medial orbital wall is located medially with respect to the maxillary ostium (Fig. 4-12). Uncinate process lateralization, hypoplasia, or even total absence is also associated with severe maxillary sinus hypoplasia.[27] Although most surgical injuries to the lamina papyracea are probably sporadic, the status of the bony orbital walls should be noted on the screening sinus CT report.

Postoperative orbital soft-tissue or osseous injury is best evaluated with direct coronal and axial CT imaging (or by using reformatted coronal images acquired from axial images using a multidetector scanner) with review of both soft-tissue and bone window settings. If orbital infection or abscess is suspected, the addition of intravenous contrast may facilitate the differentiation of phlegmon from frank abscess (Fig. 4-13). MR imaging is less sensitive in detecting small bony defects in the thin lamina papyracea, but it clearly delineates the orbital soft tissues, including the optic nerve.

Blindness from direct optic nerve injury is a rare but a devastating FESS complication. The optic nerve is vulnerable during dissection in the lateral recess of the sphenoid sinus and when there is a pneumatized superolateral recess of the sphenoid sinus. The sinus wall may be markedly thinned or even nonexistent, especially when the sphenoid sinus is excessively pneumatized.

As previously mentioned, pneumatization of the anterior clinoid process and resultant protrusion of the optic canal into the sphenoid sinus, which occurs in 8% of the population, is a potential risk factor and should be noted when seen on a preoperative sinus CT scan. The Onodi cell, a posterior ethmoid cell within the upper sphenoid sinus, occurs 3% to 15% of the time and may predispose to optic nerve injury when the FESS procedure involves the sphenoid sinus.[4] Surgical dissection in the sphenoid sinus is not commonly performed during most FESS procedures, but occurs when there is extensive polyposis or isolated sphenoid sinus disease. Optic nerve injury, therefore, is rare, and if the intraorbital optic nerve is injured, the anatomic surgical landmarks were not appreciated by the surgeon. Sporadic reports of intraorbital optic nerve transection are rare.[28]

Radiographic evaluation of the patient presenting with post-FESS symptoms suggesting orbital complications should include a thin-section CT scan performed in the

coronal and axial planes. On CT, penetration into the orbit through the lamina papyracea is indicated by proptosis, obliteration of orbital fat planes, orbital emphysema, retrobulbar hematoma, and distortion of the extraocular muscles or the optic nerve. Injury of the periorbital contents may be difficult to detect, but bony damage should be visible. The optic nerve should be traced in its entirety from the insertion at the posterior globe to the chiasm. The CT examination is usually diagnostic; however, if orbital and intracranial injury extent is unclear, MR imaging should also be performed.

ENDOSCOPIC SINUS SURGERY

Theory and Treatment Options

As discussed in Chapter 3, prior to the development of FESS, surgical sinus procedures were performed under the assumption that the sinus mucosa was the primary abnormality and that if the mucosa was stripped or resected, the chronic sinusitis would resolve. Poor outcomes necessitated reassessment of that theory. During the 1970s and 1980s, Messerklinger in Austria, Draf and Wigand in Germany, and Kennedy in the United States proposed that the mucosa was secondarily diseased and that a stenotic sinus ostium or a narrowed nasal cavity region obstructed the sinus, leading to hyperplastic, edematous mucosal changes.[29, 30] Stagnant sinus secretions then became infected, the mucosal changes became more severe, and the ostium was further obstructed. A cycle of mucosal swelling, sinus obstruction, infection, and worsening of mucosal swelling followed.[31] It has been shown that with improved sinus ventilation and drainage, the ciliated mucosal epithelium usually normalizes, with resolution of symptoms.[32]

Development of recurrent acute or chronic sinusitis is multifactorial, and ensuring ostial patency is only part of the treatment. Mucociliary function, transport, and clearance of secretions theoretically should normalize with the creation of a patent sinus ostium.[33] This concept likely oversimplifies treatment, as abnormal sinus ventilation, defective mucociliary function, and systemic conditions such as atopy, aspirin intolerance, and asthma also contribute to sinus inflammatory disease.

Disease or obstruction of the ethmoid sinuses is the primary event in chronic or recurrent acute sinusitis affecting the ethmoid complex, frontal sinuses, and maxillary sinuses.[34] Radiographic studies have shown that the ethmoids are the most common location for inflammatory disease. When the ethmoids are abnormal, the frontal and maxillary sinuses are more often abnormal; when the ethmoid complex is clear, the maxillary and frontal sinuses are generally normal.[31, 35–37]

Surgical procedures used in this region include widening of the ethmoid infundibulum and treating variants in the ostiomeatal complex. The most common procedure includes removal of the uncinate process and widening of the maxillary sinus ostium and infundibulum, resection of diseased mucosa in the frontal recess, unroofing the ethmoid bulla, and removing the bony septae in the anterior ethmoid complex. Total endoscopic sphenoethmoidectomy, a more extensive surgery often performed for sinonasal polyposis, involves exenteration of the ethmoid complex, opening the sphenoid sinus, and widening the ostiomeatal complex and the maxillary sinus infundibulum. Between these two procedures is a range of surgical treatments specific to each disease location (also see Chapter 3).

Endoscopic sinus surgery is individualized to each patient and to the specific sites of disease seen on nasal endoscopy and screening sinus CT. The procedure may be unilateral or bilateral and may be minimal, with only one or two sites treated (Fig. 4-14), or extensive, with multiple sites treated. In general, the trend with FESS is to operate conservatively and to do less surgery in order to preserve more mucosa.

FESS Outcomes

The success of FESS, defined as significant clinical improvement of preoperative symptoms, normalization of the mucosa and sinus ostia seen during endonasal examination, or resolution of abnormal CT findings, ranges from 78% to 95%.[8, 38–41] From 10% to 20% of patients, therefore, may report no benefit or are worse after FESS.[40, 42] There may be discordance between subjective patient-reported symptoms and the objective endonasal and/or CT examination. Alternatively, resolution or significant improvement in symptoms may be reported by the patient, with only small changes in abnormalities found at physical examination or CT imaging. In turn, the physical and CT examinations may return to normal but the patient may report continued symptoms. Subjective symptomatic relief is the primary end result, regardless of the objective examinations. The post-FESS sinus CT results, therefore, supplement the

FIGURE 4-14 Subtle post-FESS findings. On this coronal CT scan, note that the nasal septum is unusually straight, with loss of the normal mucosal contours. There has been minimal resection of the inferior turbinates. The surgery was performed to relieve symptoms of chronic nasal obstruction.

clinical data. Long-term outcome data on FESS have only recently become available. Most outcome data are short-term, with reexamination 3 months to 3–8 years after surgery. It is therefore difficult to report the efficacy of the procedure accurately, as it depends on which parameter is considered. Symptom reports are by definition subjective. The outcome depends on the degree of preoperative disease, the presence of polyposis, and which surgical procedure is performed. In summary, it is common for objective examinations to diverge from subjective patient reports, but FESS has been established as effective based on symptoms.

Recurrent acute sinusitis, chronic sinusitis, sinogenic headache, recurrent polyposis with infection or nasal obstruction, or nasal drainage are generally considered symptoms suggestive of surgical failure.[38] Sinogenic headache is defined as midface dull aching or pressure, often localized to the medial canthal region, which correlates with inflammatory disease in the ethmoid complex or ostiomeatal unit.[43] An abnormal nasal examination with mucopurulent rhinorrhea, erythema and edema of the mucosa, scarring at surgical sites, or recurrent or residual polyps, coupled with an abnormal sinus CT examination, are also considered surgical failures, especially when associated with patient symptoms.[39]

Indicators or predictors that suggest a higher likelihood of a poor outcome include smoking, allergy, asthma, aspirin intolerance, sinonasal polyps, cystic fibrosis and polyps, prior ''classic'' sinus surgery, and possibly gastroesophageal reflux disease.[40, 42, 44] Recurrent or residual sinonasal polyposis is common, occurring in about 30% to 40% of patients with polyps.[40, 42] In fact, recurrent or residual polyps are the most common endoscopic finding following FESS and one of the most common reasons patients return for revision surgery.[40, 45] As patients with polyposis, regardless of the etiology, represent a different population from patients without polyposis, outcome data for the two groups should be reported separately.

It is well established that the findings on preoperative CT images of the sinuses are not specific for sinonasal inflammatory disease, and there is no association between symptom severity and CT findings.[46, 47] The incidence of asymptomatic sinonasal mucosal thickening or opacification is high. The definition of sinusitis (adopted by the American Academy of Otolaryngology–Head and Neck Surgery, the American Academy of Otolaryngic Allergy, and the American Rhinologic Society) does not even include radiographic findings but relies solely on symptoms and physical examination findings.[48] Therefore, most surgeons would not operate on the basis of sinus CT abnormalities alone.

Sinus CT does appear to have prognostic significance for symptom resolution following FESS. The distribution and severity of disease on CT may predict the postoperative endoscopic appearance of the sinonasal region, the success of sinus surgery, and the likelihood of disease recurrence following FESS.[42, 49–51] Sinonasal polyposis with bilateral disease is the single best preoperative radiographic predictor of surgical failure.[51] Severe disease, as defined by bilateral ethmoid disease and involvement of one or two dependent sinus cavities, also is a strong predictor of FESS failure.[42]

Several objective staging systems for rhinosinusitis have been proposed and may be used to aid the patient and surgeon in making treatment decisions and predicting the surgical outcome.[42, 49, 50] The staging system at this time is an investigative tool used to quantify the degree of disease and to determine prospectively if the amount of disease correlates with surgical success. One system, termed the *Lund staging system for rhinosinusitis*, grades CT findings, anatomic variants, the surgical score, the symptom score, and the endoscopic appearance score.[52] With respect to the CT portion of the system, each sinus group is graded 0–2, with 0 indicating no abnormality, 1 partial opacification, and 2 total opacification. The ostiomeatal complex is graded 0 (not obstructed) or 2 (obstructed). Normal variants including absent frontal sinuses, concha bullosa, paradoxic middle turbinates, Haller cells, everted uncinate process or agger nasi cell pneumatization are graded 1 (present) or 0 (absent) (Table 4-1). Each side is considered separately. The CT outcome number is combined with the surgical and symptom scores for a total number to categorize the extent of rhinosinusitis and to aid the surgeon in objectively determining the need for surgery or revision FESS.

Table 4-1
LUND STAGING SYSTEM

Sinus
0—normal
1—partial opacification
2—total opacification
Ostiomeatal complex
0—no obstruction
2—obstructed
Normal variants
0—absent
1—present
Absent frontal sinuses
Concha bullosa
Paradoxical middle turbinates
Haller cells
Everted uncinate process
Agger nasi cell pneumatization

The FESS Procedure and Imaging Findings

Overview of the FESS Procedure

When assessing a postoperative sinus CT study, it is helpful to begin the interpretation with a thorough discussion of the anatomic changes that resulted from the surgery, including which structures were resected and which structures remain intact. This is especially important for the FESS procedure, as there is no routine surgery, since each operation is carefully individualized for the specific patient. After that task, the scan is assessed for residual or recurrent sinus disease. Revision FESS carries the same potential complications as initial surgery, so review of the integrity of the lamina papyracea, cribriform plate, roof of the ethmoids, and sphenoid sinus pneumatization is as important as the first preoperative sinus CT interpretation. Injury to the nasolacrimal duct occurs at a slightly higher rate with revision surgery, especially when a radical ethmoidectomy is performed.[53]

Copyright © 2003, Mosby, Inc. All rights reserved.

Understanding the FESS procedure facilitates recognition of surgical changes on the CT study. Septoplasty is an adjunctive procedure often performed during FESS to gain surgical access or treat nasal obstruction. The deviated septum can obstruct the nasal cavity, restricting endoscopic access to the ethmoid complex and ostiomeatal unit. By resecting the deviated septum or a bony septal spur, the surgeon can more easily move the endoscope posteriorly through the nasal cavity. Also, a severe septal deviation or spur can result in nasal obstructive symptoms or chronic sinusitis due to mass effect in the middle meatus, stenosing the ethmoid recess or maxillary sinus infundibulum.[54, 55]

The next step is infundibulotomy by resecting the uncinate process. A large concha bullosa or polyp is resected if it blocks access to the uncinate. Once the uncinate has been removed, the surgeon has visual and surgical access to the maxillary ostium, frontal recess, and anterior ethmoid complex. The ostium of the maxillary sinus is inspected, and obstructing polyps or hyperplastic mucosa are resected to restore normal drainage. After uncinectomy, the maxillary sinus ostium may be extended posteriorly and inferiorly, but only the minimal amount of bony resection is performed. If indicated, an ethmoidectomy is performed from anterior to posterior. The extent of this procedure is determined by the CT scan and direct visualization of disease. The ethmoid bulla is taken down as the first step in any ethmoid procedure, especially if the bulla is diseased, deviates the middle turbinate, or is so large as to obstruct the hiatus semilunaris.

If there is disease in the frontal sinus or recess, the natural ostium is identified and obstructing polyps or mucosa are resected. This is one of the most difficult areas to access and treat surgically. A large agger nasi cell may obstruct identification of the frontal recess. Other important variants here include frontal cells or superior orbital cells. The AEA must be identified prior to further dissection. The recess may be extremely narrow and obliquely angled. Generally, once the ostium is isolated, polyps or cysts can be removed, but disease located laterally is not resected. Occasionally, the bony ostium may be widened.

The ground lamella, or the posterior horizontal insertion of the middle turbinate to the lamina papyracea, separates the anterior from the posterior ethmoid cells. When significant disease is seen in the posterior ethmoid complex, the surgical dissection will be extended to treat these locations. The posterior ground lamella is carefully perforated, and the posterior ethmoid cells are entered. The roof of the ethmoid complex is identified prior to any additional surgery to avoid injury to the skull base. Careful removal of polyps, diseased mucosa, or inflammatory debris is then performed.

The usual approach to the sphenoid sinus, if necessary, is through the nasal cavity to the natural ostium at the sphenoethmoidal recess, medial to the turbinates. To gain access, it may be necessary to resect the posterior aspect of the middle turbinate.[33] A second approach is transethmoidal. In these cases, the surgeon relies on the screening preoperative sinus CT scan to be familiar with the individual anatomy in this region. It is essential that the optic nerve and internal carotid artery, and their relationship to the posterior ethmoid and sphenoid sinuses, are well understood prior to the surgical procedure.

Postoperative Findings: Expected and Complications

The postoperative CT scan reflects the surgical procedures that were performed. In the radiographic report, there should be a description of the surgical changes present and the presence of any recurrent soft tissue (likely related to scar and fibrosis), hyperplastic mucosal disease, or polyps. Radiographically, differentiation between scar, fibrosis, and diseased mucosa may not be possible.[56] One of the most common reasons for FESS failure is poor control of mucosal inflammation.[57] Recurrent symptoms following FESS are related to surgical undertreatment of a region, residual variants, restenosis from scar or adhesions, recurrent hyperplastic mucosa, or residual or recurrent polyposis. Two endoscopic findings that correlate best with a poor outcome are scarring of the ethmoids and scarring of the middle meatal antrostomy. The location of a scar or mucosal disease is particularly important to describe, especially if it occurs at a sinus ostium. Thus, significant mucosal thickening in a maxillary antrum may be secondary to recurrent stenosis at the maxillary sinus infundibulum due to a scar or a polyp. Given the theory of sinusitis, it is likely that mucosal thickening and outlet stenosis, although different in location, are causally related.

The most common CT finding in a patient with failed FESS is mucosal disease, with or without associated anatomic factors.[57] In descending order of frequency, recurrent mucosal disease is reported in the anterior ethmoid sinuses, the maxillary sinus, the posterior ethmoid sinuses, the frontal sinus, and the sphenoid sinus.[57, 58] Residual agger nasi cells, Haller cells, and ethmoid air cells are also seen in failed sinus surgery patients. Recurrent or residual polyps are commonly found, especially if polyposis was treated at the initial procedure.

The following is a location-specific description of the CT findings commonly seen when revision FESS for recurrent symptoms is being considered. These findings are summarized in Table 4-2. After septoplasty, the nasal septum on CT imaging appears straightened and the mucosa is thinned (Fig. 4-14). Bony spurs should no longer be seen. A complication of septoplasty is compromise of the septal arterial blood supply, which may lead to a septal perforation. Any bony septal interruption seen on CT should be reported by the radiologist.

The appearance of the middle turbinate is variable, depending on the extent of the surgical procedure. If a middle turbinate concha bullosa has been resected, this should be noted by the radiologist.

Table 4-2
ANATOMIC VARIABLES THAT MAY PREDISPOSE TO RECURRENT DISEASE AFTER FESS

Persistent septal deviation
Lateralized middle turbinate
Residual uncinate process
Residual ethmoid, frontal, or superior orbital cells
Scar at the maxillary infundibulum
Scar at the frontoethmoid infundibulum
Sinonasal polyposis
Residual variants—agger nasi cells, concha bullosa, Haller cells
Sinus wall osteitis

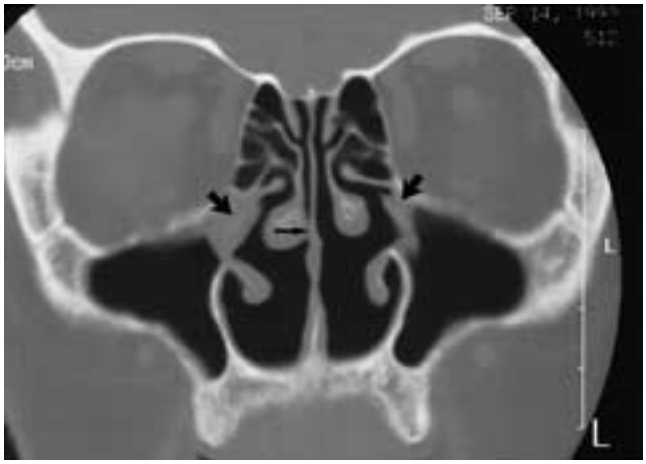
There is controversy in the surgical literature regarding whether middle turbinectomy is efficacious. Following partial middle turbinectomy, some authors report a lower incidence of recurrent frontal sinusitis, while others report a higher incidence.[59] Reasons not to resect the middle turbinate include its role in olfaction, the possible increased incidence of frontal sinusitis, and fear of mucociliary dysfunction. Most surgeons will not resect the entire middle turbinate, as the vertical insertion of the turbinate on the skull base is an important surgical landmark. As previously mentioned, a cardinal surgical rule is to stay lateral to the middle turbinate in order to avoid creating a CSF leak. If the entire turbinate is resected, this important surgical landmark is removed.

After partial turbinectomy, the middle turbinate may be intentionally opposed to the nasal septum (Fig. 4-15). Thus, the turbinate cannot narrow the middle meatus. This ''medialized middle turbinate'' contributes to maintaining a patent middle meatus and is a desired finding on postoperative CT or nasal examination. Lateralization of the middle turbinate, or scar formation between the turbinate and the lateral nasal wall, is associated with recurrent sinus inflammatory disease (Fig. 4-16).[57]

Widening of the maxillary sinus ostium and infundibulum is seen after uncinectomy, and different degrees of maxillary sinus opening are seen, depending on the extent of surgery. As described previously, only the uncinate process may be resected or there may have been a wider maxillary osteotomy. Subtotal resection of the uncinate process may be intentional, as total uncinectomy reportedly carries a risk of frontal recess scarring.[40] On the other hand, incomplete uncinectomy is a factor in recurrent sinus inflammatory disease. Any soft tissue at the maxillary ostium or infundibulum, or a residual total or partial uncinate process, should be noted by the radiologist. Synechiae or scar at the natural ostium are common postoperative findings (Figs. 4-15, 4-16).[40]



VIEW IMAGE

FIGURE 4-15 Recurrent symptoms, probably due to functional and flow changes after extensive FESS. Postoperative findings on this sinus coronal CT scan include a septoplasty, resection of most of the inferior turbinates, and a medialized right middle turbinate (*black arrows*). There is soft tissue in both maxillary sinus ostia (*thick arrows*). The soft tissue on the right is polypoid and probably represents recurrent polyps. On the left, it likely represents scar.

Middle meatal antrostomy is believed to contribute to the recirculation syndrome, which occurs when mucus that exits the natural maxillary sinus ostium enters the nasal cavity and reenters the maxillary sinus through a surgically created opening separate from the natural ostium (Fig. 4-17).[33, 40] The nasal antral window is an antrostomy surgically created immediately below the lateral insertion of the inferior turbinate and is not in continuity with the natural ostium. It was commonly performed in conjunction with the Caldwell-Luc procedure.[60] Widening or relieving obstruction of the natural ostium is currently preferred over the surgical creation of a new and separate opening in the medial wall of the maxillary sinus. Any medial maxillary sinus wall defect seen on the postoperative CT scan should be noted by the radiologist (Fig. 4-17B).

The most common CT appearance of the ethmoid complex after surgery is that of a common anterior ethmoid cavity with resection of multiple ethmoidal septations (Fig. 4-16). The ethmoidectomy may have been either partial or total, and the CT scan will reflect the procedure. Intact or residual ethmoid air cells, including the ethmoid bulla, should be reported by the radiologist, as residual cells are one of the major reasons for FESS failure (Fig. 4-18).[56] Scar formation at the ethmoid infundibulum, obstructing the sinus outflow, should be noted, as this finding is also

VIEW IMAGE

FIGURE 4-16 Recurrent sinusitis after FESS. Screening sinus coronal CT scan shows changes from septoplasty (straight septum with irregular mucosal contour), resection of the inferior aspect of both inferior and middle turbinates, total ethmoidectomy on the right, and partial ethmoidectomy on the left. There is soft-tissue scar or fibrosis at both maxillary sinus ostia (*arrowheads*), a lateralized left middle turbinate that is adherent to the lateral nasal wall (*white arrow*), and inflammatory changes in the left ethmoid complex. Minor mucosal thickening is seen in the alveolar recess of both maxillary sinuses, but the most important observation is soft tissue obliterating the anterior maxillary ostia (*arrowhead*) bilaterally. It is unclear whether this finding affects maxillary sinus clearance, but it should be mentioned by the radiologist. Incidental note is made of both anterior ethmoid arteries within anterior ethmoid canals (*black arrows*). Note the proximity of the lateral AECs near the superior oblique muscles.

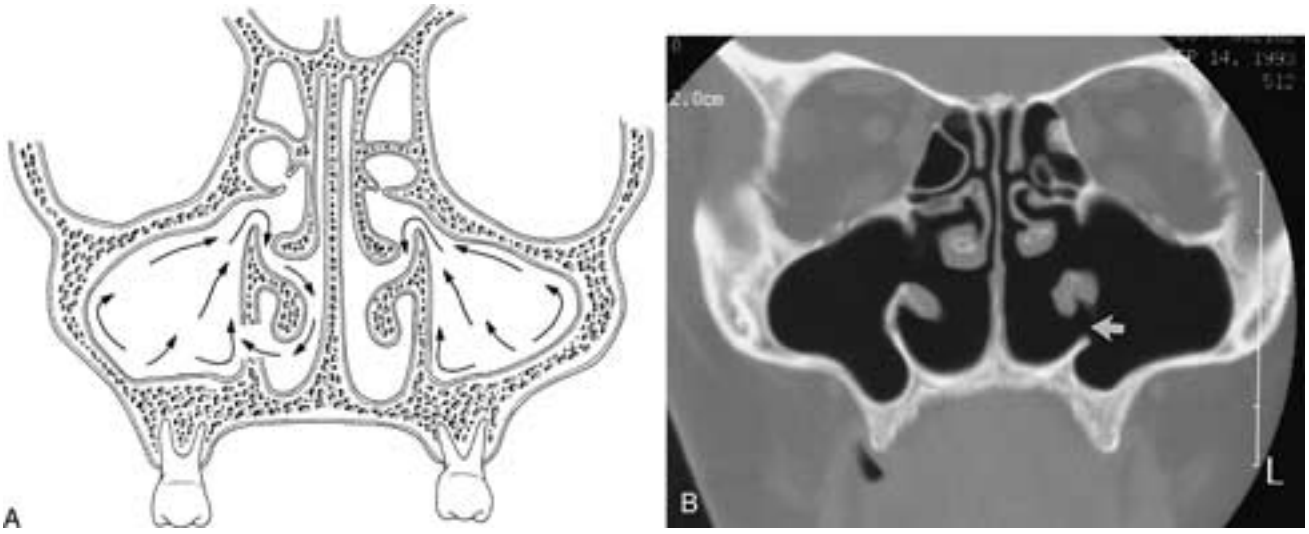
associated with failed FESS.[40] Most commonly, residual cells are located in the roof of the ethmoid complex and far posteriorly near the sphenoid sinus. Many surgeons leave these extreme cells intact in order to avoid perforation into the floor of the anterior cranial fossa or injury to the optic nerve.

Early frontal recess stenosis may be asymptomatic but should be noted, as it likely predisposes to future mucocele formation (Fig. 4-19).[42, 61] Causes of frontal sinus obstruction after FESS include residual agger nasi cells, residual frontal cells, and bony or soft-tissue obstruction of the infundibulum. Persistent ethmoid sinus disease is also a significant cause of recurrent frontal sinus disease, and prior ethmoidectomy is reported to be associated with frontal sinus disease.[42] Some of these outcomes appear discordant, and clearly long-term follow-up is necessary to understand and clarify what appear to be contradictory outcomes.

Recurrent frontal sinus disease following FESS is a difficult clinical problem. Resistant frontal sinusitis has been traditionally treated by an osteoplastic flap procedure, an external surgical approach that obliterates the sinus cavity (see Chapter 7).[62] Alternative transnasal endoscopic approaches to the frontal sinus have been proposed, and early results appear promising.[61, 63, 64] The most commonly performed procedure, termed a *Draf-type drill out* or *modified intranasal Lothrop procedure*, involves resecting all anterior ethmoid air cells and the uncinate process near the frontal recess and performing an endoscopic frontal sinusotomy. On CT, the frontal recess will appear widened and resection of the structures described will be seen. A more extensive Draf procedure will include resection of the inferior interfrontal sinus septum, the superior nasal septum, and the frontal sinus floor to the level of the orbit. This procedure, generally reserved for the most recalcitrant disease, creates a large anatomic opening with the goal of preventing recurrent stenosis.

The worst outcome based on symptoms, clinical examination, and the post-FESS CT scan, occurs in patients with extensive sinonasal polyposis. The failure rate in this group, reportedly as high as 75%, is so high that most series report diffuse polyposis outcomes separately from those in patients without polyps or with only a few polyps (Fig. 4-20).[42] Aspirin intolerance, asthma, and atopy are often seen with polyposis, suggesting a systemic but poorly understood association.[65] It has been proposed that polyposis is a systemic disease, thereby explaining the higher rate of recurrence.[38] The common CT findings seen in this group of patients are recurrent severe mucosal thickening and polyps in both operated and nonoperated sinuses and in the nasal cavity. These patients with sinonasal polyposis, with or without fungal involvement, often undergo multiple endoscopic procedures, and as the surgical risk rises with each operation, the radiologist should be particularly vigilant in assessing the lamina papyracea and anterior bony skull base.

Dense sclerotic new bone in a previously operated cavity is a common finding in patients who have failed FESS (Fig. 4-21). Similar changes may be seen in the bone of the middle



VIEW IMAGE

FIGURE 4-17 Recirculation syndrome. **A**, Coronal diagram of the sinonasal cavity at the level of the ostiomeatal unit. Middle meatal antrostomy is believed to contribute to the recirculation syndrome, which occurs when mucus that exits the natural maxillary sinus ostium enters the nasal cavity and reenters the maxillary sinus through a surgically created opening separate from the natural ostium (right side). The nasal antral window is an antrostomy surgically created immediately below the lateral insertion of the inferior turbinate and is not in continuity with the natural ostia. Any middle maxillary sinus wall defect seen on the postoperative CT scan should be noted. Note the normal mucociliary pattern on the left beating toward the natural ostium. **B**, Coronal CT scan. Note the patent middle meatal antrostomy on the left (*arrow*). There is also nearly complete resection of the inferior turbinates. No recurrent sinus inflammatory changes are noted. The meatal antrostomy, turbinate resection, and extensive loss of mucosa may contribute to abnormal sinus ventilation and function, resulting in nasal dryness and crusting simulating recurrent sinusitis.

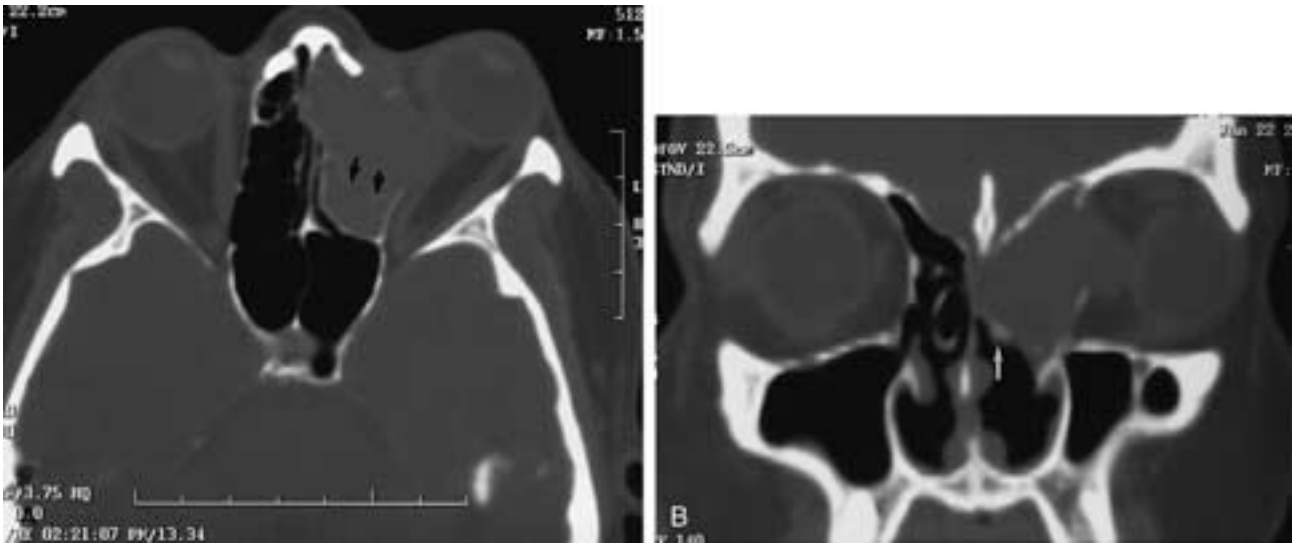
VIEW IMAGE

FIGURE 4-18 Recurrent sinusitis, preoperative scan prior to revision surgery. **A**, Coronal CT scan. On the right side, note the residual uncinate process (*black arrow*) and inflammatory hyperplastic mucosa in the maxillary sinus. Hyperplastic mucosa is seen along the uncinate process and the residual anterior ethmoid air cell (*e*), contributing to infundibular stenosis. On the left side, the inferior aspect of the middle turbinate (*short white arrow*) is lateralized and adherent to the residual uncinate process (*long white arrow*). Note the residual ethmoid air cell (*e*). There is asymmetry of the ethmoid roofs, with the left roof (*black arrowhead*) 8 mm lower than the right (*white arrowhead*). **B**, Coronal CT scan posterior to **A**. There are residual ethmoid bullar cells (*b*) bilaterally, and infundibular stenosis with adhesions between the middle turbinate and the lateral nasal wall on the left (*short arrow*) and the bulla and lateral nasal wall on the right (*long arrow*). Incidental note is made of an unprotected anterior ethmoid artery (*arrowhead*), without a bony canal, in the right ethmoid roof.



VIEW IMAGE

FIGURE 4-19 Post-FESS frontoethmoidal mucocele, likely due to postoperative frontal recess stenosis. **A**, On the axial CT scan, 1-mm slice thickness, the left ethmoid sinus is airless and expanded. Deossification of the medial orbital wall results in poor visualization of the bony wall, and there is intraorbital, extraconal extension of the mucocele. Note the posterior displacement of the anterior wall of the posterior ethmoid sinus (*arrows*). **B**, The high-resolution coronal reformation shows a prior septoplasty, resection of both inferior turbinates, with only the inferior aspect of the left middle turbinate remaining (*arrow*), and the large mucocele. Recurrent frontoethmoidal recess stenosis from synechiae or mucosal disease likely led to the mucocele. The patient complained only of proptosis.

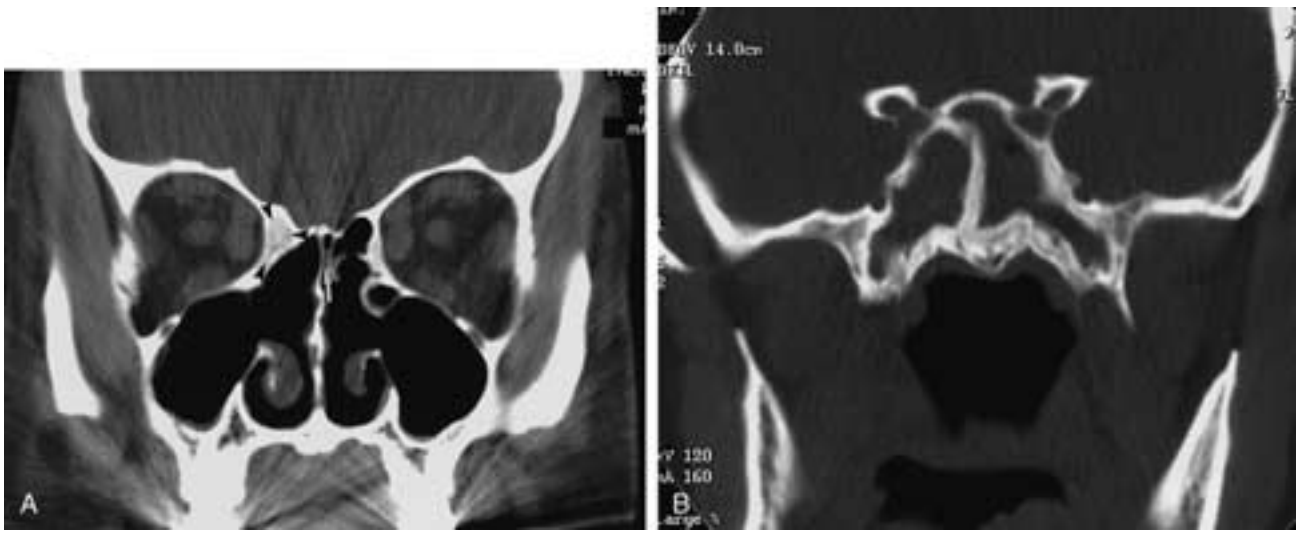
VIEW IMAGE

FIGURE 4-20 Recurrent polyposis. **A**, On this coronal CT scan, note the maxillary sinus hypoplasia, prior Caldwell-Luc defects (*arrows*), and diffuse recurrent mucosal thickening. There is extensive osteitis involving all the sinus cavity walls and even the bone of the inferior turbinates (*arrowheads*). **B**, Coronal CT scan posterior to **A**. Inflammatory mucosal changes are seen medial to the right middle turbinate (*arrowhead*). This area is almost never approached surgically, as injury to the perforated cribriform plate (*white arrows*) can result in CSF leak. The sinus walls are so dense and sclerotic that the anterior ethmoid artery canals (*black arrows*) are well seen.

turbinate.[66] Histopathologic study reveals an increase in bone physiology with bone resorption, neogenesis, and fibrosis, similar to chronic osteomyelitis.[67] Chronic inflammatory changes are seen even when the overlying mucosa is normal. It is not clear whether this is a response to chronic infection or surgery or whether it is causal in the continuing cycle of sinusitis. These poorly understood osseous changes should be noted on screening sinus CT because of their frequent coexistence with chronic sinusitis. The bony changes may be isolated to a portion of a sinus, may be present throughout the sinus walls, or may be strategically located at the sinus ostium. This is an area of active basic research because of the potential implications for long-term antibiotic treatment.[67]



VIEW IMAGE

FIGURE 4-21 Failed FESS, two separate patients with osteitis. **A**, Coronal CT scan. At this level the maxillary ostia and infundibulum are widely patent, and the residual left middle turbinate is adherent to the nasal septum (*arrow*), a desired postoperative result, as the ethmoid infundibulum is patent. Note that at this level the entire right middle turbinate, even the vertical portion, has been resected. This observation should be reported in the dictation, as an important surgical landmark is gone. The dense sclerosis within the right ethmoid complex (*arrowheads*) is seen and represents a new finding. The significance of this physiologic bony change is not well understood, but it likely relates to chronic osteitis and inflammatory changes and is a common finding in patients with recurrent symptoms after FESS. **B**, Coronal CT scan. In this patient with recurrent sphenoid sinusitis after FESS, note the sclerosis of the sinus walls and the intersphenoidal septum.

ACUTE RHINOSINUSITIS

Sinonasal inflammatory disease is a ubiquitous illness, and virtually everyone experiences multiple episodes of either a viral, bacterial, allergic, vasomotor-related, or reactive type of sinonasal inflammation. Of these, it is the common cold that is the most frequent infectious malady of the upper respiratory tract, and it is one of the major causes of absenteeism from work. The primary clinical manifestations of this viral infection are clear, watery, profuse nasal discharge and nasal stuffiness that usually persist for less than a week. The evoked inflammatory changes are completely reversible. The most common causative agents are rhinoviruses, parainfluenza and influenza viruses, adenoviruses, and respiratory syncytial virus.[1]

The typical cold is rarely imaged and it remains primarily a viral rhinitis with little significant sinusitis. If imaging is obtained, it usually shows thickening of the nasal fossae

mucosa, swelling of the turbinates, and little, if any, sinus mucosal disease.

If the clear nasal discharge becomes mucopurulent, a secondary bacterial infection has developed. This occurs when the swollen nasal or sinus mucosa causes obstruction of a sinus ostium. This causes the oxygen tension within the sinus to decrease and the normal bacterial flora becomes altered, resulting in a secondary-type acute bacterial sinusitis. Direct sinus puncture or open surgical biopsies yield the most accurate bacterial cultures for a sinusitis, as these procedures prevent contamination by the nasal flora.[2] The most commonly implicated pathogens from such studies are *Streptococcus pneumoniae* (pneumococcus), *Haemophilus influenzae*, and beta-hemolytic streptococcus. Rarely, *Staphylococcus aureus* and *Pseudomonas* infections occur.[3] Pathogenic anaerobes are rare in acute sinusitis. However, in cases of chronic sinusitis with persistently low intrasinus oxygen tensions, anaerobes predominate. These anaerobes include peptostreptococci, *Bacteroides sp. lanchnicus*, and fusobacteria.[4, 5] In the case of the maxillary sinus, it is estimated that 10% to 20% of the infections are secondary to dental infection or are the result of a complication of a tooth extraction.[6]

When imaging sinus mucosal inflammation from any cause, the inflamed mucosa enhances and there are variable amounts of submucosal edema and increased surface secretions (Fig. 5-1). There is no apparent prognostic relationship between the clinical response to the cause of the inflammation and the degree of submucosal edema or the amount of sinus secretions. An important point to note is that normal sinus secretions and submucosal fluid are each about 95% water. As these two fluids in varying amounts comprise the major response to sinonasal inflammation, inflammation is characterized by a water dominated response. This is important when MR imaging inflammation, where the signal intensities will be those of water.

If the sinus ostium is only transiently obstructed, with conservative treatment the bacterial sinusitis often resolves within 4 to 7 days. Sinusitis can cause pain over the affected sinus: cheek pain is associated with an antral infection, frontal pain may be caused by a frontal sinusitis, pain between the eyes may indicate an anterior ethmoid sinusitis, and suboccipital pain is often the result of a posterior ethmoid or sphenoid sinusitis. By comparison, a true headache is estimated to occur in only 3% of patients with sinusitis. Conversely, only 7% of headaches are the result of sinusitis.

Although a generalized headache can occur, it is unusual and may reflect intracranial spread of the sinonasal infection. Due to a rich venous emissary plexus between the posterior frontal sinus mucosa and the meninges, acute frontal sinusitis is most likely to spread intracranially, and clinical manifestations of this may be present in as few as 36 to 48 hours after initial presentation. Sphenoid and ethmoid sinusitis are the next most likely to progress to intracranial

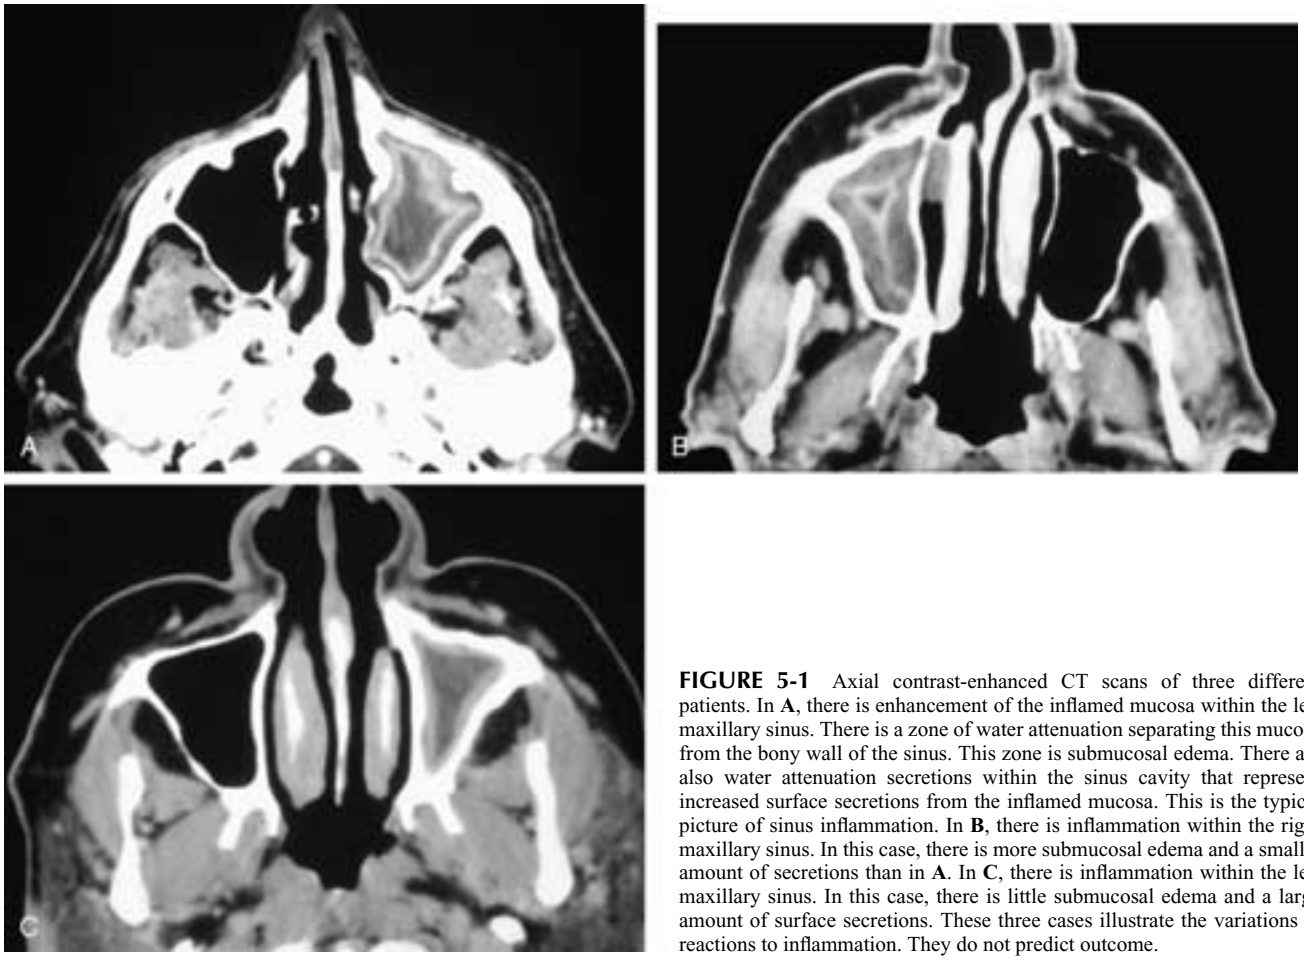

FIGURE 5-1 Axial contrast-enhanced CT scans of three different patients. In **A**, there is enhancement of the inflamed mucosa within the left maxillary sinus. There is a zone of water attenuation separating this mucosa from the bony wall of the sinus. This zone is submucosal edema. There are also water attenuation secretions within the sinus cavity that represent increased surface secretions from the inflamed mucosa. This is the typical picture of sinus inflammation. In **B**, there is inflammation within the right maxillary sinus. In this case, there is more submucosal edema and a smaller amount of secretions than in **A**. In **C**, there is inflammation within the left maxillary sinus. In this case, there is little submucosal edema and a large amount of surface secretions. These three cases illustrate the variations in reactions to inflammation. They do not predict outcome.

FIGURE 5-2 Axial (**A**) and coronal (**B**) contrast-enhanced CT scans on a patient with a right ethmoid sinusitis, a right orbital cellulitis, and air in an abscess (*arrow*). The globe is proptotic and laterally displaced. There is no gross defect in the right lamina papyracea. In **C**, a patient developed a right orbital cellulitis secondary to a right ethmoid sinusitis. The infection spread via the right superior ophthalmic vein (*arrow*) to the cavernous sinus, across the sella's vascular bed to the left cavernous sinus, and then retrograde into the left orbit via the left superior ophthalmic vein (*arrows*). In **D**, there is a left ethmoid sinusitis that spread through the lamina papyracea into the left lacrimal saccular area (*arrow*) and presented clinically as an acute dacryocystitis. This is a case of pseudodacryocystitis secondary to an ethmoid sinusitis.

infection. Intracranial extension from maxillary sinusitis rarely occurs.

Because headache may be the symptom most often suggesting intracranial extension of sinusitis, the causes of headache have been studied. In one study of 92 patients with headache, migraine was found to be the most frequent cause of headache. In decreasing order of occurrence, the other causes were tension-type headache, sinusitis, and epilepsy. The percentage of the findings relevant to headache on CT scans, MR studies, Waters' projections, and electroencephalograms were, respectively, 4.2%, 33.3%, 16%, and 25%. Observed imaging findings associated with headache included sinusitis, dilatation of the basal cistern, dilatation of the temporal horn of the lateral ventricle, pseudotumor cerebri, and mesiotemporal sclerosis. The conclusion of this study was that the most important points in evaluating these patients are taking a proper history of headache, obtaining a thorough physical and neurologic examination, and performing an MR imaging study.[7]

However, the cause of a headache may not be found on imaging studies. In another study on both HIV-seropositive and HIV-seronegative patients over a 2-year period, 50% of all subjects reported a headache. However, the frequency and characteristics of the headaches were not different between the two groups, and the headaches were neither more frequent nor different in HIV-seropositive individuals with advanced immunosuppression. There was no correlation between headache and abnormal CSF parameters, cranial MR imaging abnormalities, including the presence of sinusitis, or the use of zidovudine.[8]

Acute bacterial sinusitis is more likely to spread to the orbits than extend intracranially (Fig. 5-2A–C) (also see Chapter 9). The thin lamina papyracea and the absence of valves in the anterior and posterior ethmoidal veins allow unobstructed intraorbital spread of acute bacterial infection. Sphenoid and maxillary sinusitis are the next most likely to spread to the orbits, followed by frontal sinusitis. Older reports erroneously implicate frontal sinusitis as a major source of orbital infection. However, such cases are more likely the result of supraorbital ethmoid sinusitis. Of all orbital infections, nearly two-thirds arise secondary to sinusitis.

Copyright © 2003, Mosby, Inc. All rights reserved.

The contiguous spread of inflammation from infected ethmoid sinuses into the surrounding tissues of the lacrimal drainage system can produce symptoms easily confused with those of acute dacryocystitis (Fig. 5-2D) (also see Chapter 10). Cases of pseudodacryocystitis arising from anterior ethmoiditis have been reported, and the importance of differentiating these etiologies was noted, as the surgery of choice is an anterior ethmoidectomy rather than dacryocystorhinostomy when such pseudodacryocystitis proves unresponsive to antibiotic therapy.[9]

Acute bacterial sinusitis is the result of sinus ostial obstruction. Thus, bacterial sinusitis occurs as a sinus-by-sinus event rather than as a generalized systemic process. It is more common to find contiguous unilateral bacterial sinusitis than it is to encounter pansinusitis. Even with pansinusitis, one or more sinuses are usually more severely affected. Therefore, as a general rule, asymmetric sinusitis is a hallmark of bacterial disease. By comparison, diffuse, nonlocalized pansinusitis is more often found in allergic patients, presumably as a result of a systemic process rather than a localized obstruction.

With reference to acute maxillary sinus disease, periodontal disease is associated with a twofold increase in the risk of developing maxillary sinusitis. Recognition of this relationship is especially important in the clinical management of patients, particularly those planning to have implant surgery.[10]

Necrotizing fasciitis is a rare condition that usually affects the trunk, perineum, and limbs. Head and neck involvement is particularly rare, and in most cases it is secondary to orbital or dental infection. A case of craniofacial necrotizing fasciitis secondary to a maxillary sinusitis was reported. Although treated intensively and aggressively, the patient died 1 week after hospital admission. This report emphasizes the importance of early diagnosis and aggressive management in these cases.[11]

The relationship between acute sinusitis and ischemic stroke is also largely unexplored. However, the anatomic proximity of the paranasal sinuses and the internal carotid artery suggests that inflammation of the sinuses could easily extend to the intracranial vasculature. Four patients with acute ischemic stroke and extensive disease of the paranasal sinuses have been reported. All of these patients had strokes involving the cavernous internal carotid artery and all also had extensive sinus disease, especially involving the sphenoid sinus. This report suggests that, although rare, there may be a relationship between acute paranasal sinusitis, particularly sphenoid sinusitis, and ischemic stroke.[12]

Sphenoid sinusitis may also cause optic neuritis. Possible mechanisms of nerve damage include direct spread of infection, occlusive vasculitis, and bony deficiency in the wall of the sinus. Patients presenting with isolated optic neuritis and atypical headache should have a CT or MR study. An opaque sphenoid sinus in the context of decreased visual acuity should not be dismissed as coincidental, but considered as pathologic and the patient referred for drainage (Fig. 5-3).[13]

Evaluation of potential acute graft-versus-host disease (AGVHD) after bone marrow transplantation is becoming increasingly common. Imaging of the paranasal sinuses is part of the fever workup for these patients. In a retrospective case control study of 45 adults receiving allogeneic or matched bone marrow transplantation, AGVHD developed in 28 (62%). All patients had paranasal sinus imaging with either CT or plain films for evaluation of possible sinusitis, and no direct correlation was found.[14] On the other hand, another study showed that CT of the paranasal sinuses is advised in patients suffering hemoblastoses, with an increased risk of infectious complications during the transplantation phase, because pathologic findings can be expected in 21% of these patients. The authors emphasized that the diagnosis of and therapy for an acute sinusitis are especially important prior to allogenous bone marrow transplantation.[15]

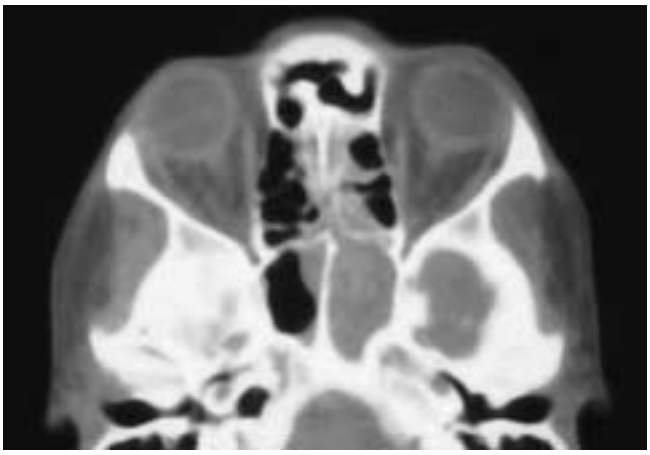

FIGURE 5-3 Axial CT scan of a patient with left optic neuritis and a chronic suboccipital headache. The brain was normal on CT and MR studies. There is opacification of the left sphenoid sinus, and minimal mucosal disease is present in the the right sphenoid sinus and in both ethmoid sinuses. The patient had no symptoms referable to the sinuses. Surgery revealed sinusitis, and in the immediately postoperative period the patient's headache and visual findings resolved. The walls of the sphenoid sinus were intact.

AIR-FLUID LEVELS

Air-fluid levels are most common in the maxillary sinuses and are the result of acute bacterial sinusitis with obstruction of the sinus ostium. The obstruction does not allow normal sinus drainage to occur, and the sinus secretions accumulate within the sinus cavity. Although bacterial sinusitis is the most common cause of a paranasal sinus air-fluid level, it probably occurs in only 25% to 50% of patients with this disease (Figs. 5-4 to 5-6). In prior decades, when antral lavage was a common therapy for acute obstructive bacterial sinusitis, air-fluid levels could be seen within the sinus for 2 to 4 days after the lavage, reflecting the presence of residual saline that was used in the lavage. If lavage is performed, follow-up films should be obtained at least 7 days after the lavage. A persistent air-fluid level after 7 days indicates renewed sinus obstruction.

Nasogastric tube placement is common in patients with loss of consciousness, severe trauma, or who are post operative. Prolonged supine positioning, and irritation and edema caused by the tube, interferes with normal sinus drainage, and within 24 hours air-fluid levels can be seen in

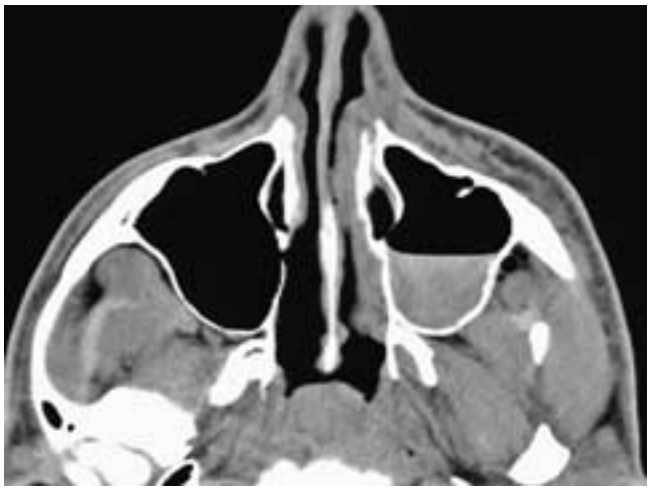
FIGURE 5-4 Waters view shows a left maxillary sinus air-fluid level (*arrow*) with minimal mucosal thickening within the sinus. The remaining sinuses are normal. This patient had acute bacterial sinusitis.

any or all of the paranasal sinuses.[16] After several days the sinuses may become completely opacified with secretions, and imaging will reveal an apparent pansinusitis. These sinus opacifications usually clear within a few days after the nasal tube is removed and the patient has started to vary head position.

A mucosal tear or rent can occur with physical trauma, regardless of whether a sinus wall fracture occurred. Often, such a tear occurs after blunt trauma, and an air-fluid (air-blood) level usually indicates the presence of a mucosal tear. However, a coincidental acute sinusitis in the affected sinus may cause clinical confusion, which can be avoided by performing a CT or MR study. On CT, intrasinus blood is



VIEW IMAGE

FIGURE 5-5 Axial CT scan shows an air-fluid level in the left antrum in this patient with a clinically acute sinusitis. The attenuation of the fluid is that of watery ''mucous secretions.'' Also note the slight cellulitis in the left facial soft tissues, as evidenced by thickening of the skin, subcutaneous fat, and facial musculature.

VIEW IMAGE

denser than normal mucosal edema and inflammatory secretions, and since this is an acute process, desiccated secretions within the sinus are not a consideration (Fig. 5-7). On MR T1-weighted images, intrasinus blood (after 24 to 48 hours) has a high signal intensity (Fig. 5-8). By comparison, acute inflammatory related tissues have a low T1-weighted signal intensity. Thus sectional imaging can resolve questionable cases of sinus hemorrhage.[17, 18]

Barotrauma is a disorder that affects aviators, parachutists, divers, and caisson workers. It most often is associated with an upper respiratory tract infection (34%) accompanied by swelling of the mucosa around the sinus ostium. In these patients, this anatomic substrate prevents rapid pressure equilibration across this ostium, which creates a negative intrasinus pressure that causes rupture of submucosal vessels and sinus hemorrhage. Mucosal and submucosal hemorrhage occurs, usually associated with pain over the involved sinus. Epistaxis is the second most common symptom. The frontal sinus is involved in 68% of cases, the

FIGURE 5-8 In **A**, an axial CT scan shows central areas of increased attenuation in both maxillary sinuses, separated from the sinus walls by a thin zone of mucoid attenuation. This picture is consistent with either chronic sinusitis with desiccated sinus secretions, fungal sinusitis with a mycetoma, or sinus hemorrhage. In **B**, a T1-weighted MR image, the central area of each maxillary sinus has high signal intensity consistent with hemorrhage. The surrounding low signal intensity material is mucosa and fresh secretions.

ethmoid sinus in 16%, and the maxillary sinus in 8%. On plain film studies, mucosal thickening can be detected in the frontal sinuses (24%), the ethmoid sinuses (15% to 19%), and the antrum (74% to 80%); however, an air-fluid level (present in 12% of cases) appears to only be seen in the maxillary sinus.[19]

Hemorrhage can also result from bleeding disorders such as von Willebrand's disease, in which bleeding tends to occur at mucosal surfaces, and possibly Oler Weber Rendu syndrome. Hemophilia, on the other hand, tends to involve internal bleeding and is not associated with a sinus air-fluid level. Coagulation disorders and acute leukemia may also produce air-fluid levels. Rarely, chemically induced sinusitis can produce an air-fluid level. Chromates and other industrial pollutants have been implicated in such cases. Despite the rhinitis and rhinorrhea associated with allergy, few air-fluid levels are seen.

The significance of an air-fluid level varies, depending on the paranasal sinus involved. In the frontal sinuses an air-fluid level usually means acute bacterial sinusitis (Fig. 5-9). As previously mentioned, intracranial complications can occur readily, often within 48 hours (Fig. 5-10).[20] The clinician should be alerted immediately regarding a frontal sinus air-fluid level, as these patients require prompt, vigorous treatment, often including intravenous antibiotics. Failure of a clinical response and the beginning of resolution of the air-fluid level within another 48 to 72 hours after the onset of treatment usually mandates sinus trephination. Such aggressive therapy usually avoids any intracranial complications.

An ethmoid sinus air-fluid level is rare and usually is not associated with either trauma or acute infection. However, if an ethmoid mucocele ruptures and partially drains into the nasal fossa, an air-fluid level may result in what is invariably a mucopyocele. This unusual occurrence is the most common cause of an ethmoid air-fluid level (Fig. 5-11A).

In the sphenoid sinus an air-fluid level may indicate the presence of acute sinusitis or nasal cavity obstruction. An air-fluid level in a supine and/or unconscious patient may only indicate poor sinus drainage. In a trauma patient, a sphenoid sinus air-fluid level may also signify the presence of either hemorrhage or CSF from a skull base fracture. Most often these fractures involve the floor of the anterior cranial fossa or the mastoid portion of the temporal bone, not the sphenoid sinus walls. In the case of anterior skull base fractures, because the dura is firmly attached to the bone, a fracture here is likely to cause a dural rent and resulting CSF rhinorrhea.[21] With the patient supine, the CSF drains back into the sphenoethmoidal recess and into the sphenoid sinus. In the case of a temporal bone fracture with an intact tympanic membrane, the CSF drains into the hypotympanum of the middle ear, escapes via the eustachian tube into the upper nasopharynx and nasal fossa, and then into the sphenoid sinus. Thus CSF rhinorrhea with or without a

sphenoid sinus air-fluid level may reflect a temporal bone fracture.

CSF fluid may also enter the sphenoid sinus spontaneously, usually through a dehiscence in the medial aspect of the roof of a lateral sinus recess (Fig. 5-11B,C). A CSF leak associated with a pituitary tumor or surgery is rare.

CHRONIC SINUSITIS

Chronic sinusitis results from either persistent acute inflammation or repeated episodes of acute or subacute sinusitis. It is estimated that up to one third of patients with acute sinusitis develop some evidence of chronic sinusitis. The chronic disease can result in an atrophic, sclerosing, or hypertrophic polypoid mucosa. These varied mucosal changes most often coexist with one another and with areas of acute inflammation of either an infectious or allergic etiology. Because chronically inflamed and scarred mucosa loses some of its ciliary function, it becomes less resistant to future infection so that a vicious cycle of infection and reinfection may occur in patients with chronic sinusitis. The bony sinus walls surrounding a chronically infected sinus usually become thickened and sclerotic with reactive new bone formation. This bony response is found with all chronic inflammations regardless of etiology and presumably is a response to both the increased local blood flow associated with inflammation and periosteal involvement. However, on CT, care must be taken when viewing a sinus with mucosal disease at narrow ''soft-tissue'' windows, as bone appears denser and wider than it truly is. This is a problem of the algorithms of all CT manufacturers, and the actual bone density and size are best seen on wide window settings (Fig. 5-12).

Epithelial hyperplasia and mucosal infiltration of leukocytes are common features of chronic rhinosinusitis. It has been shown that the epithelium can produce chemoattractant cytokines that may contribute to leukocyte infiltration in rhinosinusitis. Mucosal IL-8 expression is increased in patients with chronic rhinosinusitis, and the level of expression directly correlates with disease severity.[22]

Chronically obstructed sinus secretions can result in four possible outcomes: (1) the sinus obstruction can abate and the sinus will clear, (2) the obstructed secretions can remain indefinitely within the sinus as watery secretions, (3) the entrapped secretions can become desiccated, or (4) the secretions can progressively accumulate and a mucocele can develop. These entities will be described further in the section on Imaging.

Nasal polyps are uncommonly associated with chronic inflammation and when present are most often solitary. By comparison, multiple nasal polyps are common with allergic-type rhinosinusitis. Although mucosal thickening in the nasal fossae, sphenoid, ethmoid, and frontal sinuses is more common in patients with acute asthma than in control subjects, maxillary sinus mucosal thickening is no more common in asthmatic patients than in control subjects.[23]

Allergic Sinusitis

Nearly 10% of the population has allergic rhinosinusitis, which generally involves the sinuses symmetrically. The most common form is seasonal pollinosis, and the prevalent form in North America is ragweed allergy. Spores, molds, and mites are also important antigens.[24] Allergic reactions are manifestations of type I immunologic disorders, which reflect an IgE reagin-antibody reaction, with a resulting release of mediators that produce sneezing, nasal obstruction, and watery rhinorrhea. Profuse secretions associated with nasal obstruction can result in some retained secretions and eventual infection.[24] Thus the coexistence of bacterial and allergic sinusitis is not uncommon. The resulting hypertrophic, thickened, and redundant allergic sinus mucosa is often referred to as *hypertrophic polypoid mucosa*, which is less capable than normal mucosa of resisting subsequent infections. Rarely, in the maxillary sinus, hypertrophic mucosa can become so redundant that it prolapses into the nasal fossa, simulating an antrochoanal polyp.[25] The difference is that in these unusual cases the prolaped tissue is simply redundant mucosa rather than an actual polyp.

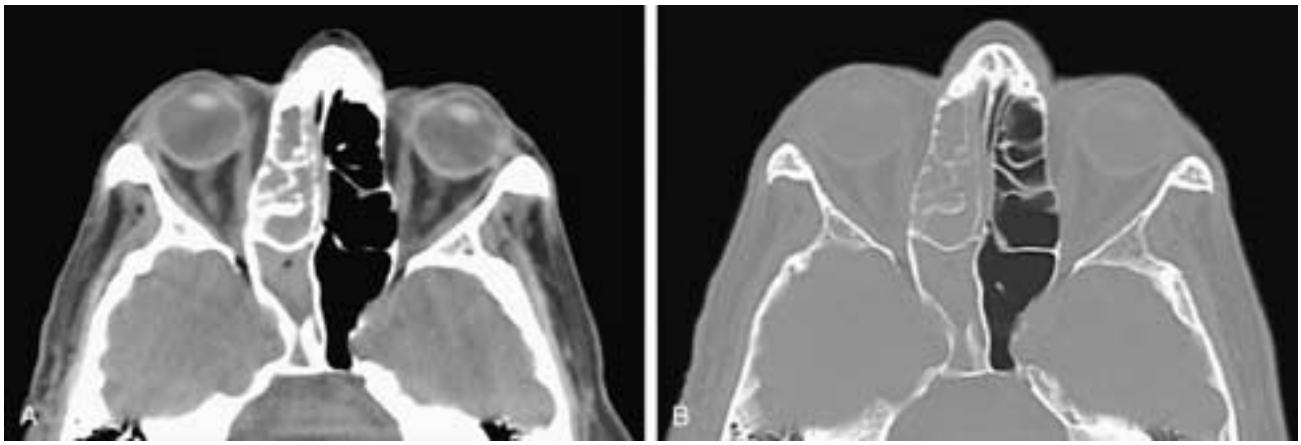

FIGURE 5-12 Axial CT scan (**A**) shows opacification of the right ethmoid and sphenoid sinuses. The ethmoid septae and the surrounding bone appear thickened and sclerotic on this narrow ''soft-tissue'' windowed image. This might imply a chronic process. However, in **B**, the same image viewed at wide ''bone'' window settings, the bone appears normal and similar to that on the left side. This is the more accurate assessment of the bone size and density in this patient with clinically acute sinusitis.

VIEW IMAGE

Tissue eosinophilia is a characteristic histologic feature of allergic sinusitis in children and adults, especially those with asthma. However, eosinophilia is not sensitive for allergic sinusitis and does not correlate with the severity of mucosal thickening, as seen on CT scans.[26]

As mentioned, infectious rhinosinusitis is caused by a variety of agents that produce both acute and chronic inflammation that may be associated with secondary polyp formation. These patients commonly have a secretory IgA deficiency.[27] There is evidence to suggest that fluctuating glucose levels occurring in concert with other factors (allergy, infection) may promote nasal polyps in patients with diabetes.[28] In general, nasal polyps in children are uncommon, and 29% of such cases are associated with cystic fibrosis. Between 10% and 20% of children with cystic fibrosis have nasal polyps. Thus, the presence of chronic sinusitis and nasal polyps in a child should prompt an investigation to rule out cystic fibrosis.[29, 30]

The triad (aspirin intolerance) of aspirin usage, nasal polyps (often highly destructive), and bronchial asthma is less commonly encountered, as the generalized use of acetaminophen products has replaced aspirin usage. This triad is associated with severe destructive-type nasal polyposis. In general, about 20% of patients with nasal polyps have asthma, and conversely, about 30% of asthmatic patients have polyps.[29–31] Nickel workers who have worked 10 years or more in nickel-refining facilities have a 4% incidence of inflammatory nasal polyps with squamous metaplasia and dysplasia. They are at increased risk of developing carcinomas in the lung, nasal fossa, and larynx.[32]

Vasomotor Rhinitis

Vasomotor rhinitis refers to the symptoms of nasal congestion, watery discharge, and nasal polyps occurring in the absence of obstruction, ciliary dysfunction, or allergy. These patients do not have evidence of IgE-mediated disease and do not have positive skin tests. Instability of the autonomic nervous system has been implicated as the underlying problem. Vasomotor rhinitis can be stimulated by emotional stress, endocrine imbalance, atmospheric pressure changes, irritants, and as a reaction to medications. Among conditions associated with vasomotor rhinitis in some reports are antihypertensive medications, abuse of nasal sprays and drops, birth control pills, pregnancy and ''premenstrual colds (estrogen related),'' hypothyroidism (2% to 3% of patients), emotional stress, poor environmental temperature control, irritants (dust, gases, chemicals, aerosol cosmetics, and air pollutants such as sulfur dioxide and tobacco), recumbent position, nasal airway exclusion (postlaryngectomy, choanal atresia, marked adenoidal hypertrophy), Horner's syndrome, and systemic disorders such as superior vena cava syndrome, cirrhosis, and uremia.[33] When considering causes of nasal obstruction, vasomotor rhinitis is often a diagnosis of exclusion. Although no consistent imaging findings have been reported in patients with vasomotor rhinitis, one could expect at most to see mild swelling of the turbinates, some increased nasal secretions, and mild mucosal thickening within the sinuses.

Fungal Sinusitis

A variety of fungal diseases involve the sinonasal cavities. These include aspergillosis, mucormycosis, candidiasis, histoplasmosis, cryptococcosis, coccidioidomycosis, North American blastomycosis, rhinosporidiosis, and myospherulosis.[34] There are four clinicopathologic classifications of mycotic sinonasal disease: (1) acute invasive fulminant disease, (2) chronic invasive infection, (3) noninvasive mycotic colonization (''fungus ball'' or mycetoma), and (4) allergic mycotic sinusitis. These four types of infection can be seen with any fungus but are most commonly a result of *Aspergillus* infection. Not infrequently, the pathologic diagnosis of mycotic disease requires heightened clinicopathologic suspicion. From a pathologic viewpoint, hyphae may be sparse in allergic mycotic sinusitis, being found only beneath the mucosal surface or only within the mucin. In early invasive sinusitis, hyphae may be confined to the vessels. A thick sinonasal mucus of unusual color (green, brown, or black) should raise the clinical suspicion of a mycotic infection. Hyphal fragments may be impossible to classify without culture confirmation, and pathologic correlation is always necessary to distinguish clinical infection from laboratory contamination. The sinonasal fungal diseases can be classified as being either fungal hyphal diseases or fungal yeast forms (also see the section on imaging).

Fungal Hyphal Diseases

Aspergillosis infection is caused by the fungus *Aspergillus*, a member of the Ascomycetes class. It is a ubiquitous organism frequently found in soil, decaying food, fruits, and plants. The spores are also common contaminants of the respiratory tract and the external auditory canal. *A. fumigatus* is the major human pathogen; however, *A. flavus* and *A. niger* can also cause human infections. Of the culture-confirmed cases of mycotic sinusitis, 87% contained some *Aspergillus* species as the sole pathogen or as a copathogen.[35]

Acute fulminant *Aspergillus* sinusitis occurs in the immunosuppressed, especially granulopenic patients with hematologic malignancies. Initial complaints are those of acute sinusitis such as nasal discharge, sinus pain, and/or periorbital swelling. Clinical examination of the nasal cavity and palate shows pale, ischemic tissue that may progress to gray and blackened, gangrenous tissue. The ability of *Aspergillus* to invade vessels is aided by its production of elastase and proteases. As the infection spreads through vascular and neuronal routes, orbital nerve invasion occurs, progressing to blindness. Treatment involves surgical debridement and antifungal agents. Treatment with antifungal medications usually includes itraconazole or one of the newer oral azoles (voriconazole).[36] The tissue at debridement is typically bloodless due to hyphal-related thrombosis. The prognosis for these patients is usually grave. *Aspergillus* sinusitis is not uncommon in immunocompromised patients and is unusual in immunocompetent patients.[37]

Chronic invasive *Aspergillus* sinusitis can be found in normal hosts living in highly endemic areas such as the Sudan or Saudia Arabia. Asymptomatic nasal colonization

Copyright © 2003, Mosby, Inc. All rights reserved.

has also been demonstrated. The Middle Eastern cases are quite distinctive in that they occur in immunologically normal patients, probably because of prolonged exposure to large inocula of spores. In the United States, chronic invasive sinusitis is most commonly seen in mildly immunosuppressed patients such as diabetics. Most patients respond to surgical debridement and antifungal therapy.[38–40]

A mycetoma is the benign fungal hyphal colonization of a cavity or space. In the sinonasal tract, a mycetoma may develop in response to changes in the local microenvironment such as occur after surgery, radiotherapy, and anecdotally, in association with smoking marijuana. Patients with mycetomas may complain of chronic sinusitis, or they may be entirely asymptomatic. Therapy is conservative curettage, but benign recolonization may occur.

Patients with allergic mycotic sinusitis have a history of allergic sinusitis, polyposis, and possibly allergic asthma. Serum eosinophilia, elevated IgE, cutaneous sensitivity to fungal antigens, and the presence of fungus-specific serum precipitins support the diagnosis of allergic mycotic sinusitis. Conservative curettage and systemic steroid therapy are the recommended treatments.[41] Histopathologically, hyphae are sparse and noninvasive, and they may be seen only after special stains are examined. Culture confirmation is necessary because the hyphal fragments do not allow definitive identification. Because of the environmental prevalence of *Aspergillus*, it is the assumed cause of most allergic fungal sinusitis cases. However, the dematiaceous fungi may also cause allergic sinusitis.

Rhinocerebral mucormycosis (also phycomycosis or zygomycosis) is a disease caused by several genera of the fungi of the class Zygomycetes (formerly Phycomycetes) and the family Mucoraceae. The genera, in order of decreasing frequency, are *Rhizopus*, *Mucor*, and *Absidia*. The members of the class Zygomycetes can be found in decaying fruit (especially those with a high sugar content), vegetables, soil, old bread, and manure. The zygomycetes have been isolated sporadically in some studies of indoor environments. Various spices, herbal teas, and birdseed harbor *Rhizopus* and *Absidia*. Iatrogenic subcutaneous wound infections by *Rhizopus* can be caused by Elasto-plastR brand bandages.

The Zygomycetes have a propensity for infecting uncontrolled diabetic patients as well as patients with hematologic malignancies (e.g., acute leukemia); chronic renal failure and acidosis; malnutrition; cancer; cirrhosis; and prolonged antibiotic, steroid, or cytotoxic drug therapy. *Rhizopus* grows favorably in an acidic, high-glucose environment, which relates to its elaboration of ketone reductase. The acidosis, in addition to providing a favorable growth environment, also further impairs polymorphonuclear leukocyte function.

Sinus mucormycosis occurs predominantly as an invasive rhinocerebral infection. The clinical course may be acute, invasive, and fulminant, just as in aspergillosis. The organism tends to spread rapidly from the nasal fossa to the paranasal sinuses and the fungus invades blood vessels, causing endothelial damage that initiates thrombosis, ischemic and hemorrhagic infarction, and purulent inflammation. Eventually the orbits and cavernous sinuses are invaded via the ophthalmic vessels. Invasion of the base of the brain is an end-stage event, and the entire progression of the disease can occur in only a few days. Perineural invasion can also occur, usually along the branches of the trigeminal nerve.[42]

Diabetic patients may develop a more chronic invasive sinusitis, which is amenable to debridement and antifungal therapy. In AIDS patients, whose neutrophil function is largely intact, mucormycosis is actually a rare infection.[43] Clinically, black, crusting, necrotic tissue is seen over the turbinates, septum, and palate. By comparison, in immunosuppressed patients, focal ischemic areas may be found instead of the more typical black crusts. In the cases occurring in nondiabetic patients, pulmonary and disseminated infections are more common. Among survivors there is a high incidence of blindness, cranial nerve palsies, and hemiparesis. The best therapy is adequate surgical debridement and systemic intravenous amphotericin B.[34]

Mucormycoses has been documented in nondiabetic, nonimmunosuppressed patients. A preexisting foreign body, marijuana use, or prior surgery or radiotherapy may be predisposing factors in these unusual cases.[44, 45]

Fungi from the order Entomophthorales, which are also Zygomycetes, may cause granulomatous rhinoentomophthoromycosis in normal hosts from tropical climates. Cases have been reported in U.S. inhabitants with no history of travel, and Entomorphthora species have been isolated from algae, ferns, insects, and reptiles (*Basidiobolus ranarum* and *B. haptosporus*). Entomophthorales infection begins as a submucosal nasal mass that slowly expands, causing enormous erosion, destruction, and deformity of the nasal and labial soft tissues. The rhinocerous-like midface expansion is similar to that seen in advanced cases of rhinoscleroma.

Pseudallescheria boydii (formerly called *Allescheria boydii*) is the current nomenclature for this fungus of the Ascomycetes family. It is a ubiquitous organism most commonly found in rural areas, and it is isolated from soil, poultry, cattle manure, and polluted waters. *P. boydii* sinusitis, which may be fulminant and lethal, has been reported in immunocompromised patients. It has also been described in normal patients and may resolve with adequate therapy. Like aspergillosis, this disease may be either saprophytic or invasive. *P. boydii* has been reported to involve the maxillary, ethmoid, and sphenoid sinuses. The present treatment of choice is miconazole, with surgical debridement if necessary.[46, 47]

Fungal Yeast Forms

The yeasts of the genus *Candida* are part of the normal mucocutaneous flora. However, under certain circumstances, *Candida* may produce either a minor or a life-threatening disease. Minor infections may result as overgrowths in patients on antibiotic therapy. The more severe *Candida* infections occur almost exclusively in patients with compromised immune systems. Today, candidiasis represents the most common and most lethal of the opportunistic fungal infections among immunocompromised patients.[34] Most infections are caused by *Candida albicans*, but *C. tropicalis*, *C. stellatoidea*, and *C. krusei* may also cause disease. When the paranasal sinuses are affected, it is usually in otherwise healthy patients who have been on broad-spectrum antibiotics. The maxillary sinuses are almost exclusively involved, and orbital and intracranial

Copyright © 2003, Mosby, Inc. All rights reserved.

complications are rare. Infections can also occur after maxillary trauma. The treatment of choice for the sinus disease is antral lavage with topical nystatin.[48]

Histoplasma capsulatum is present worldwide and is endemic in the midwestern, central, and southeastern regions of the United States. Exposure to *H. capsulatum* occurs through exposure to aerosolized bird or bat droppings and contaminated soil or fertilizers. As with most inhaled mycotic pathogens, the most common manifestation of histoplasmosis is a subclinical pulmonary infection, usually a function of a small exposure source and the state of patient immunity. Patients may develop acute pneumonia after massive inhalation. Chronic cavitating and fibrosing pulmonary infection, sclerosing mediastinitis, and disseminated infection with bone marrow and adrenal involvement (resulting in Addison's disease) are more serious sequelae of histoplasmosis.

Before the AIDS epidemic, disseminated histoplasmosis was rarely seen, and when it was encountered, it was usually in elderly patients or those immunosuppressed by chemotherapy or hematologic malignancy. Today, disseminated histoplasmosis and extrapulmonary histoplasmosis in the face of HIV seropositivity are included as one of the criteria for AIDS. Disseminated histoplasmosis presents with fever, septicemia, pneumonia, hepatic or renal failure, CNS infection, or skin lesions. It is thought to be due to reinfection from an endemic focus or, less frequently, reactivation of latent disease. Head and neck manifestations of disseminated disease in AIDS patients include cervical adenopathy, pharyngitis, tonsillitis, and ulcerating oral lesions. Non-AIDS patients may also develop histoplasmosis of the oral cavity and larynx. Rarely, there can be involvement of the nasal mucous membranes, resulting in edema and nasal obstruction. Even more rarely, pansinusitis can occur. The current treatment of choice is amphotericin B.[34, 49, 50]

Cryptococcus neoformans is a ubiquitous yeast of worldwide distribution. It is associated with pigeon excreta and pigeon nesting sites, and human infection results from inhalation of aerosolized droppings.[34] It may cause asymptomatic, localized pulmonary granulomata. Cryptococcal pneumonia or disseminated infection can develop in immunosuppressed patients. Cryptococcal meningitis occurring in the AIDS population is thought to follow respiratory infection, and the frontal and maxillary sinuses have been documented as primary sources of infection. Isolated sinonasal disease is uncommon but is identical to that of histoplasmosis, and the treatment is the same as for histoplasmosis.[51, 52]

Coccidioidomycosis is a disease caused by the dimorphic fungus *Coccidioides immitis*. The pathogenesis and clinical manifestations of the disease are almost identical to those of histoplasmosis. *C. immitis* is endemic in the southern United States and in northern Mexico, as well as a few sites in Central America and South America. It has been estimated that 20% of cases reported yearly are diagnosed outside the endemic areas, thus widening the relevance of this organism. *C. immitis* is extremely infectious. Illness ranges from subclinical infections to disseminated and often lethal infections, depending on the patient's immune status, infectious dose, nationality, and other factors such as pregnancy. Most of the head and neck disease affects the laryngotracheal axis, with or without concurrent pulmonary disease. Sinonasal involvement is rare.[53, 54]

Myospherulosis is not a fungal disease but rather an iatrogenic condition that is caused by the interaction of red blood cells with petrolatum, lanolin, or traumatized human adipose tissue.[34] Microscopically, large sporangium-like sacs filled with spherules are produced that can be mistaken for a fungus. The disease was first recognized as skin lesions in East Africans; however, in the United States the disease has involved the nose, paranasal sinuses, and middle ear. In these patients there was always prior surgery (i.e., the Caldwell-Luc procedure), and the surgical defect was packed with gauze impregnated with petrolatum. It is important to recognize this disease as an innocuous iatrogenic process so that it is not confused with a true fungal disease and given unwarranted therapy.

CYSTS AND POLYPS

The most frequent complications of inflammatory rhinosinusitis are polyps and cysts. The retention cyst is the most common, being found incidentally on routine plain film examinations in about 10% to 35% of patients. A mucous retention cyst results from the obstruction of a submucosal mucinous gland, and the cyst wall is the duct epithelium and capsule of the gland itself.[55, 56] Although by strict pathologic criteria a retention cyst can be called a *mucocele*, the radiographic and clinical findings of these two entities are sufficiently different to merit distinction (see the section on mucoceles). Mucous retention cysts can occur in any paranasal sinus, along any wall, but are most commonly found in the maxillary sinus. As mentioned, they usually are an incidental imaging finding.

Serous retention cysts result from the accumulation of serous fluid in the submucosal layer of the sinus mucosal lining. These cysts tend to occur in the base of the maxillary sinuses, and the lining of a serous retention cyst is the elevated sinus mucosa. By contrast, as mentioned, the lining of a mucous retention cyst is the actual obstructed ductal epithelium.

By comparison to serous retention cysts, polyps result from an expansion of fluids in the deeper lamina propria of the Schneiderian mucosa in the nasal fossa and paranasal sinuses. These polyps may result from allergy, atopy, infection, or vasomotor impairment.[57] Paranasal sinus and nasal polyps have an identical histology. Allergic polyps tend to have a significant population of eosinophils, more than what is usually seen in inflammatory polyps, and such polyps may be associated with allergic mucin, comprised of a sea of eosinophils in mucin and Charcot-Leydin crystals, which are the result of eosinophil degranulation. As mentioned, the associated allergic sinusitis tends to cause diffuse symmetric disease rather than localized disease. It has been suggested that there is an interaction between eosinophils and fibronectin that may play a role in edema formation, which contributes to the growth of nasal polyps.[58]

Inflammatory and allergic polyps rarely bleed and are not damaged by manipulation or compression. However, fibrosis and neovascularization of polyps (especially nasal polyps) can result in a vascularized polyp that pathologically mimics an angiofibroma. Anatomic and imaging

Copyright © 2003, Mosby, Inc. All rights reserved.

features that distinguish a vascularized polyp from an angiofibroma include the following: (1) the former is located in the nasal fossa rather than in the nasopharynx, (2) the polyp does not extend into the pterygopalatine fossa, and (3) the polyp is easily removed. These polyps are poorly vascularized, further distinguishing them from angiofibromas.[59]

As mentioned, nasal polyps are most often associated with allergy and, when found in this clinical setting, they are usually multiple. Histologically there are a number of secondary changes that can occur with these polyps: infarction, surface ulceration, mucoid liquefaction, stromal cell atypia, and metaplasia of the surface epithelium. Carcinoma arising from surface metaplasia is very rare and is almost always associated with an external carcinogenic promoter, either smoking or some occupationally related promoter. On the other hand, atypia of stromal cells may be misinterpreted as a malignancy because of its microscopic resemblance to rhabdomyosarcoma or myxoid sarcoma.[57, 60]

Polyps are the most common expansile lesions in the nasal cavity. Although they usually are small and cause little deformity, if left unattended in the presence of progression, they can become highly deforming. Eventually they may remodel, disrupt, and destroy the central facial region. They can destroy the medial antral walls, cause hypertelorism, and break through intracranially either via the roof of the nasal cavity and ethmoid complex or via the sphenoid sinus. This marked degree of destruction may be found among medically underserved patients with intractable allergic polyps (primarily aspirin intolerance) and patients with a high level of denial. Destruction secondary to polyposis is an indolent process, causing little if any pain. Although surgery is the treatment of choice for large polyps, in allergic patients desensitization has in some cases shown dramatic results in reducing the number and size of these polyps.[61] Etiologically, in addition to allergy, polyps have been associated with vasomotor rhinitis, infectious rhinosinusitis, diabetes mellitus, cystic fibrosis, aspirin intolerance, and nickel exposure.[61]

On occasion a maxillary sinus polyp may expand and prolapse through the sinus ostium, presenting as a nasal polyp. These are referred to as antrochoanal polyps, which represent 4% to 6% of all nasal polyps. Most are unilateral solitary lesions, but bilateral antral inflammatory disease is found in as many as 30% to 40% of cases. Almost 8% of these patients have additional nasal polyps, and 15% to 40% of patients have a history of allergy.[60–62] These latter statistics have prompted the suggestion that there is an etiologic relationship to allergy, but this theory has not been borne out. Most antrochoanal polyps occur in teenagers and young adults. If such polyps are surgically snared in the nasal fossa like routine nasal polyps, without regard to their antral stalk, 20% to 30% of them will recur, usually within 2 years.[61] The proper treatment is via a Caldwell-Luc or endoscopic intraantral approach.

Ethmoidochoanal and sphenochoanal polyps have also been described. The latter are rare. The etiology of these polyps appears to be similar to that of the antrochoanal polyp.[63]

The Pediatric Patient

In the pediatric patient, there is little correlation between active infection and sinus opacification and mucosal thickening. This is particularly true in children less than 4 years of age and especially in children less than 2 years of age, in whom tears, retained secretions, and normal redundant mucosa may account for these findings.[16, 64–67] In all such pediatric patients, identification of thickened sinus mucosa should be carefully evaluated in the clinical setting prior to making a diagnosis of active infection. Tissue eosinophilia is characteristic of chronic pediatric sinusitis, especially in children with asthma. However, the presence of allergy does not predict tissue eosinophilia, and the degree of tissue eosinophilia does not correlate with the severity of mucosal thickening as seen on CT scans.[68]

Persistent sinusitis in a pediatric patient may indicate the presence of cystic fibrosis. In these patients, persistent nasal obstruction and sinusitis often lead to hypoplasia of the frontal sinuses, presumably secondary to insufficient aeration. Additional conditions to consider in children with repeated episodes of sinusitis include immune deficiency syndromes, HIV infection, allergic sinusitis, unusual allergies such as aspirin intolerance, and immobile cilia syndrome. In ruling out the latter syndrome, it may be useful to recommend that the clinician submit a brush biopsy specimen from the lateral nasal wall for electron microscopy. Brush biopsy specimens submitted in glutaraldehyde are superior to routine forceps specimens for visualizing the ultrastructure of ciliated cells. Lastly, children under the age of 10 years rarely develop allergic nasal polyps. Thus the presentation of a nasal polyp in the first few years of life should raise the suspicion of an encephalocele, while the appearance of nasal polyposis should suggest the diagnosis of cystic fibrosis.[69, 70]

The HIV-Positive Patient

In recent decades, there has been considerable interest in the prevalence and type of paranasal sinus inflammatory disease in HIV-positive patients.[71] Minimal sinus inflammatory disease may be clinically significant for these patients, and early treatment should be initiated. HIV specifically affects T helper lymphocytes, as well as monocytes, macrophages, and other parenchymal cells. One of the many ripple effects of the loss of T helper cells is dysfunction of the B lymphocytes, which results in unusually severe bacterial infections. The B cells are unable to respond normally to antigenic stimulation due to the loss of lymphokine-induced stimulation. AIDS patients may develop sinusitis secondary to the usual bacterial agents (*H. influenzae*, *S. pneumoniae*, *S. viridans*, *Moraxella catarrhalis*, coagulase-negative staphylococci, *Staph. aureus*), plus other bacteria (*Pseudomonas aeruginosa* and *Legionella pneumophila*) that are considered opportunistic pathogens and rarely cause sinusitis in normal hosts.[72, 73]

MUCOCELES

A mucocele is the most common expansile lesion to develop in a paranasal sinus. Pathologically, it is defined as a collection of mucoid secretions surrounded by mucus-secreting respiratory epithelium. Although histopathologically both lesions consisit of mucous secretions surrounded by an epithelial lining, mucoceles and retention

Copyright © 2003, Mosby, Inc. All rights reserved.

cysts are distinguished by their clinical and imaging features.[74]

The retention cyst, as mentioned, is a spherical mucoid-filled cyst that develops when a mucous gland of the sinus mucosa becomes obstructed. The epithelium of the duct and gland capsule is the cyst wall. These cysts are common, usually incidental findings identified in at least 10% of people. They are within the sinus cavity, and almost always some surrounding sinus cavity air remains. Although these cysts can occur in any sinus, they are most common in the maxillary sinus and they rarely cause any remodeling of the sinus wall.

By comparison, a mucocele develops from the obstruction of a sinus ostium or a compartment of a septated sinus, and the wall of the mucocele is the sinus mucosa. The sinus is completely filled and airless, and the sinus cavity is expanded as the bony walls are remodeled outward. An expanded sinus cavity is critical to making the diagnosis of a mucocele, as without this finding, the sinus is properly referred to as an obstructed sinus. Mucoceles occur in all of the paranasal sinuses, with most developing in the frontal sinuses (60% to 65% of cases). Between 20% and 25% occur in the ethmoid sinuses, and 5% to 10% in each sinus occur in the maxillary and sphenoid sinuses.[75–77]

At first, the sinus cavity expansion results in remodeled, intact surrounding bone. However, at some point the sinus cavity may become so large that periosteal repair can no longer maintain sinus wall ossification and deossification occurs. On imaging these areas appear as absent bone, but they may be mistaken for areas of eroded bone.

Rarely, a retention cyst or polyp may become so large that it completely fills the antrum and widens the infundibular region, making distinction from an early mucocele impossible. However, this is of no clinical significance, as the surgical treatment of these lesions is the same.

The classic mucocele is a sterile lesion that presents with signs and symptoms resulting from the mass effect of the lesion. Thus, frontal sinus mucoceles are commonly associated with inferolateral proptosis, a superomedial orbit mass, frontal bossing, nasal obstruction (unilateral or bilateral), and nasal voice quality. Ethmoid mucoceles are associated with lateral proptosis, nasal stuffiness, and possibly a nasal quality to the voice. A supraorbital mucocele can cause downward proptosis, as these mucoceles arise in the mid-roof of the orbit. They also may cause a mass in the floor of the anterior cranial fossa. Maxillary mucoceles may present as a cheek mass, upward displacement of the eye, and nasal obstruction. Sphenoid mucoceles may present with decreased vision, suboccipital headache, and, rarely, fullness in the roof of the nasopharynx. Pain is uncommon and may indicate the presence of an infected mucocele or a pyocele (mucopyocele). Mucoceles have also been reported in an Onodi cell, a pneumatized anterior clinoid process, and a concha bullosa. The potential for vision loss in the two former cases must be noted.[78]

An atelectatic or silent sinus results in effects almost opposite to those of an antral mucocele. Clinically this entity is, as the name implies, asymptomatic, and is revealed only when the major ophthalmologic complication, enophthalmos, becomes evident. It is postulated that chronic sinusitis leads to ostial obstruction, which, in turn, leads to chronic negative pressure within the sinus. Eventually there is retraction of the maxillary sinus walls leading to collapse of the orbital floor and enophthalmia. The findings also include lateral bowing of the uncinate process and inward bowing of the posterior sinus wall. Awareness of this entity is important, as endoscopic osteal decompression of the sinus can avoid ophthalmologic complications.[79 80]

CORRELATION OF IMAGING AND CLINICAL FINDINGS

Occasionally, some patients may have symptoms of sinonasal inflammatory disease and normal CT and MR imaging studies. Conversely, some patients may have identifiable mucosal thickening on imaging studies and be asymptomatic. In most adult patients, there is a fairly good correlation between significant mucosal disease as seen on imaging and clinical presentation. However, for patients with treated acute sinonasal inflammatory disease, clinical improvement may occur well ahead of resolution of mucosal disease as seen on CT and MR studies. Thus, it is always treacherous for a radiologist to definitively imply that the presence of sinonasal mucosal thickening accounts for the patient's symptoms. Conversely, the radiologist should not imply that a normal sinus imaging study means that the patient does not have symptoms or is a malingerer. The radiologist's report should identify the sinuses involved and assess the degree of mucosal disease in each sinus, and reference to specific clinical symptoms should not, in general, be given.

This reference to the clinical presentation also applies to the terms *acute disease* and *chronic disease*. The presence of an air-fluid level in a patient with acute symptoms of sinonasal infection correlates well. However, many patients with acute sinusitis will not have air-fluid levels, and their imaging appearance may be indistinguishable from that of someone with subacute or chronic disease. Similarly, thickening and sclerosis of a sinus wall implies chronic, recurrent disease. It does not indicate whether any mucosal thickening in that sinus is due to acute or chronic change. Thus, without good clinical correlation, the terms *acute mucosal disease* and *chronic mucosal disease* should not be used by the radiologist. If thickened, sclerotic bone is seen, it merely indicates that there has been a chronic process in that sinus at some time. A dictation might include a statement such as ''Thickening and sclerosis of the sinus wall suggests some chronicity to the disease affecting that sinus.'' It should not qualify the acute or chronic nature of the mucosal disease presently identified within that sinus. In fact, such a sinus may contain scarred, thickened mucosa without any inflammation.

With regard to the nasal cavity, as long as, on imaging, some airway can be identified around the turbinates and the nasal septum, patients rarely complain of nasal obstruction. This imaging rule applies even in the presence of slightly enlarged turbinates and varying degrees of nasal septal deviation.

IMAGING "NORMAL" MUCOSA

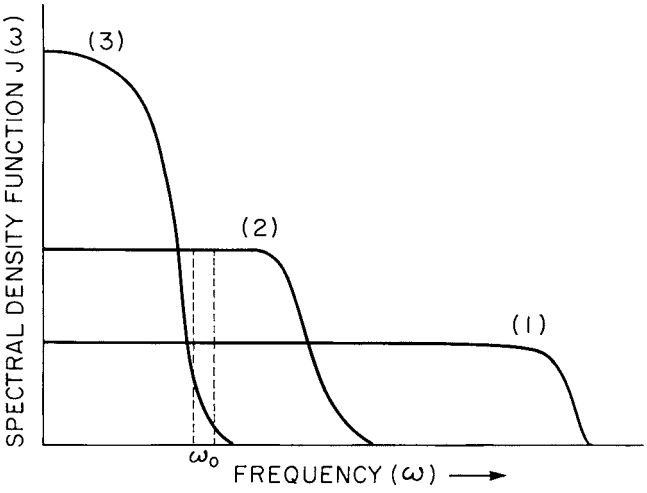
The resolution of present-day CT and MR scanners is such that physiologic mucosal thickening from the nasal

Copyright © 2003, Mosby, Inc. All rights reserved.

cycle can be routinely seen. Thus, unilateral swelling of the middle and inferior turbinates, with minimal ipsilateral ethmoid and maxillary mucosal thickening, usually reflects this physiologic event (see Chapter 3). This is true provided that the opposite middle and inferior turbinates appear small and almost crenated, and a thin airway around the swollen turbinates remains. Usually, normal sinus mucosa is so thin that it is not seen routinely on CT and MR imaging, probably because it is volume averaged out at the sinus air/bone interface. When mucosal thickening is seen incidentally on MR studies in an asymptomatic patient, the mucosa probably is minimally inflamed or scarred.

Brain MR imaging studies have confirmed the lack of imaging specificity for sinus mucosa, as mucosal thickening of up to 3 mm may be present in clinically normal patients. In addition, clinically silent focal areas of ethmoid mucosal thickening were found in 66% of patients.[81] In another series of 263 patients, clinically silent areas of mucosal thickening were found in nearly 25%.[82]

Generally, normal sinuses contain air that directly abuts the bony walls of the sinus. Thus, whenever sinus mucosa is seen at the interface between air and bone, that mucosa is thickened, and, as such, it should be mentioned by the radiologist. However, mucosal inflammation, fibrosis, or physiologic engorgement cannot be confidently distinguished. The overall evaluation of the sinus mucosa is more easily and thoroughly performed on CT and MR imaging than it is on plain films.



VIEW IMAGE

FIGURE 5-13 Diagram of a spectral distribution curve for physiologic solutions. The number of molecules at a specific frequency $J(\omega)$ is graphed against the range of frequencies (ω). Curve (1) is for water and illustrates that a wide range of frequencies is present, but there is no preponderance of molecules at any one frequency. Curve (2) shows what happens as macromolecular proteins are added to the water system. A more limited number of frequencies is present due to the large number of more slowly tumbling macromolecular proteins and because the water molecules of higher frequencies drop out as they are magnetically bound to the large proteins. Curve (3) illustrates that when a large number of macromolecular proteins are added to the systems, most of the molecules have a very limited range of slower frequencies. ω0, Lamor frequency.

MAGNETIC RESONANCE OF PROTEIN SOLUTIONS

For a specific solution, the concentration of macromolecular proteins affects the T1 and T2 relaxation times. The clinical relevance of this is that the T1-weighted and T2-weighted signal intensities of proteinaceous solutions may be quite varied for specific entities such as cysts, mucoceles, etc. Diagnostic problems in clinical interpretation can arise if this phenomenon is not understood and appreciated. Therefore, the following is a brief, simplified review of T1 and T2 relaxation times in macromolecular protein solutions.

The term *lattice* refers to the overall magnetic environment of the system being studied. A proton spin system can be excited by the addition of energy, and the most efficient way to transfer that energy to the protons is to choose an exciting pulse that is at the Larmor frequency. Once excited, the spin system tends to rid itself of the excess energy and return to an equilibrium state. The excess energy is absorbed by the lattice, and the time it takes for this process to occur is referred to as the spin-lattice or T1 relaxation time.

The most efficient transfer of this excess energy from the excited protons to the lattice occurs when the net molecular rotation of the lattice is at the Larmor frequency. Thus, if a system does not have many molecules rotating at the Larmor frequency, the energy absorption is inefficient and the T1 relaxation time is long. Conversely, if the system has most of its molecules rotating at or near the Larmor frequency, the T1 relaxation time is efficient and short. A study of the number of molecules in a system that are rotating at various frequencies yields a spectral distribution function that can be graphed as the number of molecules at a specific rotational frequency versus the range of frequencies (Fig. 5-13).

Analysis of pure water shows that these small molecules have a wide range of net rotational frequencies, but there is no preponderance of molecules at any one frequency, including the Larmor frequency. Thus pure water has a long T1 relaxation time. As large physiologic macromolecular proteins with relatively slow tumbling frequencies are added to pure water, for a variety of reasons the net rotational motion of the system slows. This effect continues as more macromolecular protein is added, until a protein concentration is reached at which there is a maximum number of molecules with a net rotation at the Larmor frequency. At this concentration the T1 relaxation time is the shortest for the system. As more macromolecular protein is added, the net rotational frequency of the system continues to slow and falls below the Larmor frequency. Consequently, for these more concentrated protein solutions, the T1 relaxation time is long. Thus, for such physiologic solutions, as one proceeds from low macromolecular protein concentrations to high concentrations, the T1 relaxation time goes from long to short to long (Fig. 5-14). This is reflected as the T1-weighted signal intensity goes from low to high to low.

With reference to the T2 relaxation time, initially, after the spin system has been excited, all of the protons can be considered as precessing at the same frequency. However, variations in the local magnetic environment of each proton cause the speed of precession to change by varying amounts, and the result of these magnetic inhomogeneities is that the

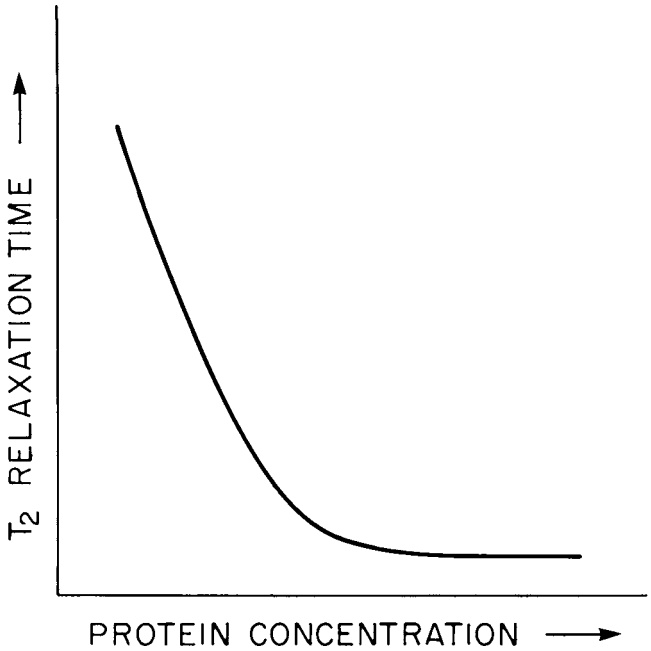
VIEW IMAGE

FIGURE 5-14 Graph of T1 relaxation time versus macromolecular protein concentration. As protein is added to a water system, the T1 relaxation slows until the net frequency of the lattice is that of the Lamor frequency. At that protein concentration the T1 relaxation time is the most efficient (shortest). As still more protein is added, the net frequency of the system slows below that of the Lamor frequency, and the T1 relaxation time again becomes less efficient.

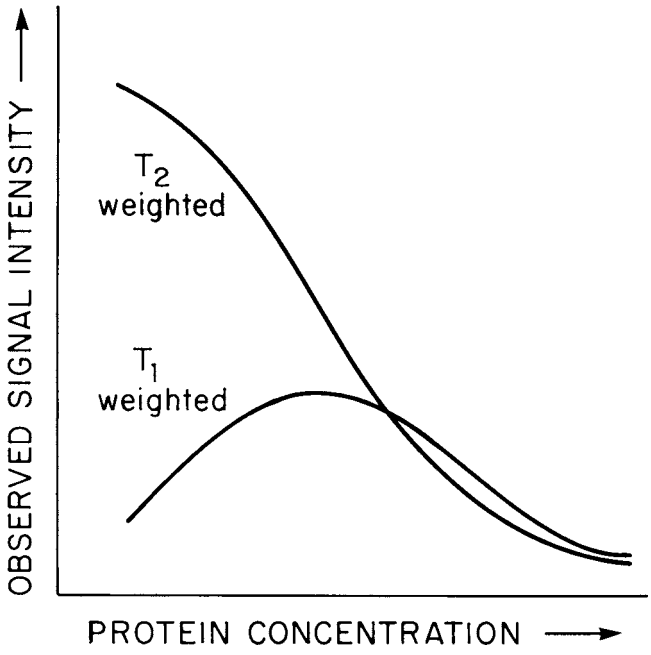


VIEW IMAGE

FIGURE 5-15 Graph of T2 relaxation time versus macromolecular protein concentration. The more protein added to the system, the lower (faster) the T2 relaxation time. This relationship holds until the system becomes a solid. In a solid, the T2 relaxation time is the fastest it can be, and it becomes a plateau.

protons start to precess at a wider and wider range of frequencies. This interaction is referred to as spin-spin relaxation or dipole-dipole dephasing, and the T2 relaxation time is a measure of this process. For pure water, all the molecules are the same, and they are moving so rapidly that they have little effect on the local magnetic fields of particular protons. Hence in pure water the excited protons precess in phase for a long time, and the T2 relaxation time is long. As macromolecular solute is added, the net frequencies slow so that there is more time for spin-spin interactions. In addition, more molecular inhomogeneity is introduced into the system. Thus, as the protein concentration increases, the T2 relaxation time decreases. However, in viscous solutions and solids, the T2 effects reach a maximum and the T2 relaxation time plateaus at its shortest time (Fig. 5-15). In fact, the T2 relaxation falls from the milliseconds range (thousandths of a second) for physiologic protein solutions to the microseconds range (millionths of a second) for solids. Such rapid dephasing does not allow any magnetic signal to be detected on MR imaging, and a signal void is observed. Lastly, when the T2 relaxation times are ultrashort in the microseconds range, this effect dominates any observed T1 relaxation, and signal voids are also observed on T1-weighted MR imaging. This phenomenon is often referred to as the *T2 effect on the T1 relaxation time*. With this simplified background, one can approach the MR signal intensities of sinonasal secretions (Fig. 5-16).

Normal sinonasal secretions form a complex solution that is in equilibrium with the interstitial fluids.[83] By weight, about 95% of these secretions is water and 5% is solids; virtually all of the solids are macromolecular proteins, predominantly (60%) mucous glycoproteins. Thus normal sinonasal secretions are predominantly water, and on MR



VIEW IMAGE

FIGURE 5-16 Graph of laboratory-observed T1-weighted and T2-weighted signal intensities versus macromolecular protein concentration. These curves reflect the relaxation times shown in Figures 5-14 and 5-15.

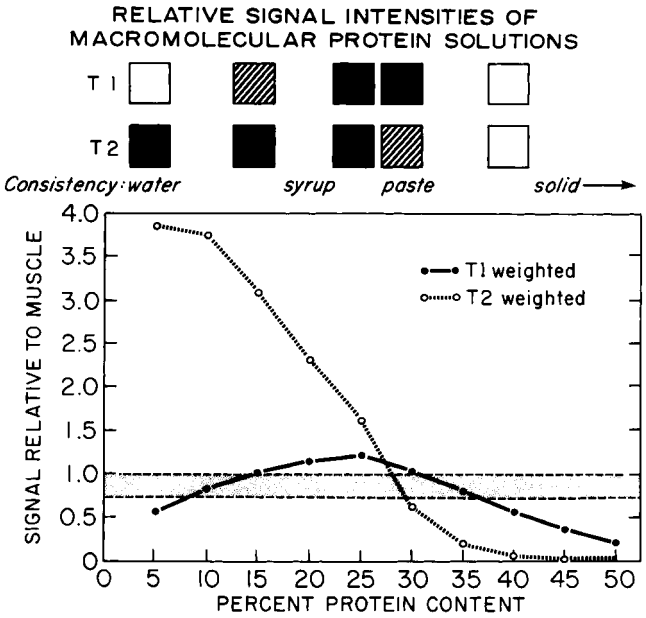
Copyright © 2003, Mosby, Inc. All rights reserved.

imaging they have long T1 and T2 relaxation times. These are observed as low T1-weighted and high T2-weighted signal intensities.

When normal sinonasal secretions become chronically obstructed, a number of predictable changes occur that alter the protein concentration, the amount of free water (that fraction of the water molecules that magnetically is independent of the effects of the macromolecular proteins), and the viscosity. These changes occur as a result of alterations in the composition and function of the obstructed sinus mucosa, which increases the number of goblet cells that are responsible for the production of the mucous glycoproteins. There is also decreased clearance of the mucous glycoproteins, and with time, the sinus mucosa also reabsorbs free water in the secretions. The result of these changes is an increase in the mucous protein concentration. The sinonasal secretions progressively change from primarily watery and serous to a thick mucus. Then they become a desiccated, stonelike mucous plug when the protein content is above about 35%.

These changes are predictable, but the rate of their evolution is highly variable, both between patients and within the various sinuses of a given patient. The protein concentration directly correlates with the T1-weighted and T2-weighted MR signal intensities of the secretions. This is shown by observing that the graphs of clinically observed T1-weighted and T2-weighted signal intensities reflect the laboratory signal intensities predicted in the prior discussion of the T1 and T2 relaxation times (Figs. 5-16 and 5-17).

As the protein content rises from 5% to about 25%, both the T1 and T2 relaxation times shorten as predicted. However, the T2 shortening is not seen on the MR images because the T2-weighted signal intensity remains high (white) throughout this range. The rise of the T1-weighted signal intensity is more easily observed on the clinical scans.



VIEW IMAGE

FIGURE 5-17 Graph of clinically observed T1-weighted and T2-weighted signal intensities versus macromolecular protein concentration. The horizontal zone of gray represents the intermediate range of signal intensity compared with that of the brain. The relationship of the relative physical consistency of the solutions to the signal intensities is shown at the top of the graph. These curves parallel those in Figure 5-16.

Protein crosslinks occur at a protein concentration of about 25% to 30%. This correlates with the increased viscosity observed clinically. Crosslinking also slows the macromolecular motion, which in turn allows dipole-dipole dephasing to become a more significant factor. As a result, the T2 relaxation time and signal intensity plummet. The T1-weighted signal intensity falls back to a low value between the protein content range of 25% to 40%. Above a concentration of 35% to 40%, virtually all of the free water has been eliminated from the secretions and direct macromolecular protein-protein binding occurs. This results in a sudden increase in the viscosity of the secretions. These semisolid and solid protein mixtures have ultrashort T2 relaxation times. These are noted first as low T2-weighted signal intensities and then as signal voids on both T1-weighted and T2-weighted MR images.

Thus, the chronically entrapped secretions become progressively thickened and concentrated, and the MR signal intensities vary with the protein concentration. This may result in anatomically similar collections having variable signal intensities. A high protein concentration can produce signal voids on both T1-weighted and T2-weighted MR images, and thus appear indistinguishable from a normal aerated sinus on MR images (Figs. 5-18 and 5-19). Although the etiology of the signal voids is different (ultrashort relaxation times for the former versus paucity of protons for the latter), the observed imaging blackness is the same. Thus the radiologist can easily underestimate the presence of such chronic desiccated secretions, and therefore the severity of the sinus disease, if MR is the only imaging examination used. CT can distinguish an aerated sinus from a chronically obstructed sinus, as dried secretions are dense (high attenuation), reflecting their high protein concentration, while air is black. CT can also diagnose chronic bone changes and differentiate some radiodensities such as calcification, ossification, or a tooth. Therefore, CT, not MR, is recommended as the first modality for patients with suspected chronic inflammatory disease.[83–85]

IMAGING

Benign Sinonasal Mucosal Disease

On plain films the earliest sign of thickened mucosa is often a hazy or vaguely ‘‘clouded’’ appearance of the involved sinus. In such cases, a thickened mucosal margin per se may not yet be identified. If this appearance is not the result of technical or extrinsic factors (the entire film looks hazy, there is overlying swelling of the soft tissues of the cheek, etc.), then this sinus is abnormal. Most commonly this appearance is the result of a combination of retained secretions and minimal mucosal thickening (Fig. 5-20). Once the mucosa is thick enough to be distinctly identifiable on plain films, the mucosa usually appears as a uniformly thick soft-tissue density zone that separates the sinus air from the bone (Fig. 5-21).

There are several situations that may falsely cause a hazy sinus appearance. For instance, haziness is often seen on plain films in the maxillary zygomatic recesses. These areas

FIGURE 5-18 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show what appears to be moderate ethmoid sinusitis with residual aeration in scattered right ethmoid cells and in the right sphenoid sinus. In a CT scan (**C**) these sinuses are completely opacified, with desiccated secretions that are separated from the sinus walls by a thin zone of mucoid attenuation. This patient had chronic sinusitis.

of the antra have less air and thicker surrounding bone than the main sinus cavity and almost always appear slightly clouded when compared with the main body of the sinus.

Maxillary sinus hypoplasia is another cause of nonspecific sinus density on plain films. However, in most cases, the associated findings of a greater downward angulation of the lateral aspect of the orbital floor and a larger ipsilateral orbit (and often a larger superior orbital fissure) allow a diagnosis to be made. However, definitive evaluation of the mucosa within a hypoplastic sinus may be impossible without CT or MR imaging. In addition, axial sectional imaging clearly allows pathology in the soft tissues of the cheek to be separated from that in the maxillary bony wall or in the sinus mucosa.[86, 87]

The unique anatomy of the ethmoid complex can also lead to underdiagnosis of pathology, as resolution of the numerous closely packed ethmoid air cells is beyond the sensitivity of plain films. The increased density associated with mucosal thickening in an isolated group of ethmoidal cells may be almost completely nullified by air-containing surrounding cells and the adjacent sphenoid sinus.

The sensitivity of the plain film examination of the ethmoid sinuses may be increased by paying close attention to the appearance of the intrasinus septa. Poorly visualized septa may belie the presence of mucosal thickening or fluid (Fig. 5-22). However, definitive diagnosis of minimal or focal ethmoid cell disease requires sectional imaging. The lack of visualization of these ethmoid septa with no obvious soft-tissue mass may also result from pneumosinus dilatans, mucocele, or previous ethmoidectomy.

In the sphenoid sinuses, minimal mucosal thickening is usually not identifiable on plain films because these sinuses are partially obscured by many overlapping bone and soft-tissue structures. Air-fluid levels can be identified on films taken in the erect position, but CT or MR is required in most cases to accurately identify mucosal disease.

Sinus opacification can be the result of a combination of mucosal thickening, increased sinus secretions, and submucosal edema. The mucosal thickening can vary from a few millimeters to a thick, hypertrophic, redundant mucosa. In some cases, increased mucosal secretions dominate, while in others, submucosal edema is dominant (Fig. 5-1). However, there seems to be no correlation between the dominant type of reaction and the clinical outcome. Rather, these various components seem simply to reflect differences in the individual response to an inflammatory insult, as previously mentioned. With reference to MR imaging, inflammation will have an impact on the MR signal intensities, as it is associated with increased sinus secretions and submucosal edema, both of which are about 95% water. Thus the presence of inflammation will be associated with the signal

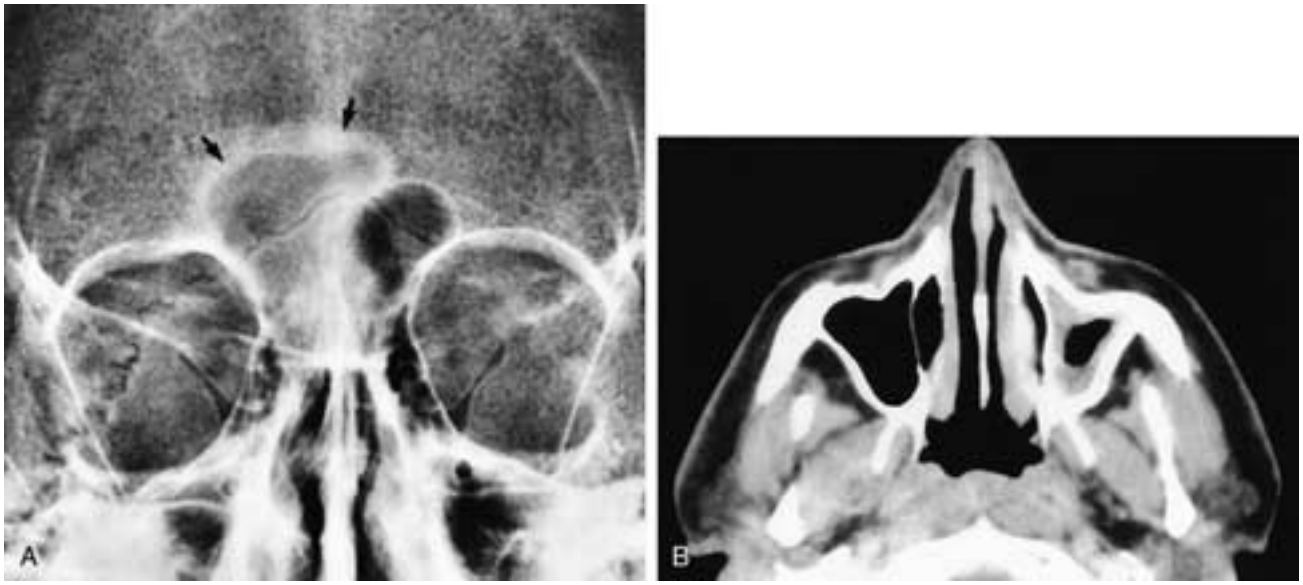
FIGURE 5-22 In a Waters view (**A**) there is opacification of a left hypoplastic frontal sinus, the left ethmoid sinuses, and both maxillary sinuses. An axial CT scan (**B**) on a different patient who had normal sinus plain films. There is localized inflammatory disease in the left anterior ethmoid cells. However, the left middle and posterior ethmoid cells and the left sphenoid sinus are well aerated. Because on a frontal film this air may negate the soft-tissue density of the anterior ethmoid disease, the frontal plain films may appear normal. Both of these patients had acute sinusitis.

intensities of water, namely, low T1-weighted and high T2-weighted signal intensities.

After several days of inflammation, increased calcium resorption from the sinus walls can be observed on plain films. The cause is unknown but may be the result of increased mucosal vascularity. Plain films show a ''washing out'' of the thin mucoperiosteal white line adjacent to each sinus cavity. This effect is most evident in the frontal and maxillary sinuses.

Conversely, when inflammation has been present for many months or years, the sinus walls become thickened by reactive bone (Fig. 5-23). In the maxillary sinus, this bone may become so thick as to decrease sinus cavity size, a finding confirmed on CT scans.

Chronic sphenoid sinusitis can also result in thickened, sclerotic surrounding bone. Often these patients complain of suboccipital pain or headaches (Fig. 5-24). Rarely, cavernous sinus thrombophlebitis and thrombosis can develop as a



VIEW IMAGE

FIGURE 5-23 Caldwell view (**A**) shows a zone of reactive sclerosis around a clouded right frontal sinus (*arrows*). This suggests that there had been chronic disease in this sinus at one time. There also is minimal clouding of the right ethmoid sinuses. This patient had chronic sinusitis. In **B**, an axial CT scan shows thickening and sclerosis of the walls of the left maxillary sinus and mucosal thickening within this sinus. The mucosal disease may be acute sinusitis, noninfected edematous mucosa, or chronically scarred mucosa. The bone reaction indicates that there has been chronic inflammation in this sinus. This patient had chronic sinusitis.

FIGURE 5-25 Coronal CT scan shows mucosal thickening in the left maxillary sinus associated with thickened, sclerotic bone in the sinus walls. However, unlike Figures 5-23 and 5-24, there are areas of rarefaction and early sequestrum formation along the upper antral wall. Minimal mucosal disease is also present in the right maxillary sinus. This patient had chronic sinusitis with osteomyelitis.

complication of sphenoid sinusitis that may lead to meningitis. Most patients with intracranial-type symptoms will initially have a CT or MR study. Such examinations should always include the skull base and paranasal sinuses to eliminate these as a source of the disease and symptoms.

Osteomyelitis of the bones of the face and paranasal sinuses is uncommon and is usually associated with localized pain. The involved bone has a mottled, irregular appearance on both plain films and CT. There may be sequestra, as well as areas of thickened and sclerotic bone (Fig. 5-25).

More commonly, osteomyelitis may be posttraumatic or iatrogenic. It is most often found following an osteoplastic flap procedure for frontal sinus inflammatory disease. A poorly vascularized and/or infected bone flap may result in osteomyelitis of the flap, a recognized complication of this procedure.

Postirradiation osteitis is rarely seen today in the facial bones because of megavoltage equipment and improved radiation treatment planning. Radiation osteitis is probably most commonly encountered in the mandible, usually in patients irradiated for carcinomas of the tongue and floor of the mouth. In patients irradiated for maxillary sinus carcinomas, the first manifestation of sinus osteomyelitis may be localized pain, swelling, and inflammation over the zygoma and maxilla, initially suggesting tumor recurrence. However, eventually a bone sequestrum is extruded, and symptoms temporarily improve. Multiple sequestra are usually extruded, and it is not uncommon for the osteitis to become clinically manifest up to 1 or 2 decades after irradiation. On CT the involved facial bones appear shattered, fragmented, and sclerotic (Fig. 5-26). Superficial sequestra should be specifically identified and localized to aid therapy.

When evaluating mucosal thickening on postcontrast CT scans, if the thickened mucosa does not enhance, it is probably not actively infected and usually is fibrotic and scarred. Active infection has a thin zone of mucosal enhancement with a variable zone of lower-attenuation submucosal edema (Fig. 5-1). If the sinus is opacified, the CT appearance shows roughly concentric rings or zones: an outer bony wall ‘‘ring,’’ a water or mucoid attenuation (10 to 18 HU) submucosal ring, a thin infected mucosal enhancing ring, and a central zone of entrapped mucoid secretions (Fig. 5-1). Although most minimal to moderate mucosal thickening is seen as a fairly uniformly thick soft-tissue zone on sectional imaging, thicker, more redundant mucosa can appear almost nodular or ‘‘wavelike.’’ In these instances, the disease tends to involve the sinus diffusely, unlike the focal nodularity often seen with tumors.

In all CT examinations, the sinuses should be viewed at wide window settings so that mucosal disease is not falsely interpreted as a hypoplastic or aplastic sinus (Fig. 5-27).

On MR imaging the thickened, inflamed mucosa typically has a low signal intensity on T1-weighted images, an intermediate intensity signal on proton density (PD) images, and a high signal intensity on the T2-weighted images (Figs. 5-18, 5-19, and 5-28). These changes reflect the high water content of the inflamed tissues. The high T2-weighted signal intensity is helpful in differentiating inflamed tissues from almost all sinonasal tumors. At most, such tumors tend to have an intermediate T2-weighted signal intensity. Dense scar or fibrosis has a low to intermediate signal intensity on all imaging sequences, a useful finding in differentiating it from inflammation and most tumors on the T2-weighted images. Unfortunately, both tumor and the vascularized scar tissue/granulation tissue that develops after surgery have similar signal intensities, and they cannot, at present, be confidently differentiated on MR imaging.

Unilateral swelling of the middle and inferior nasal turbinates, especially in the absence of concurrent paranasal sinus disease, probably reflects the normal nasal cycle. In these cases, a thin zone of air remains, separating the turbinates from the nasal septum and the lateral nasal wall. If this air space is not present, the turbinates probably are pathologically enlarged. Clinical correlation can help

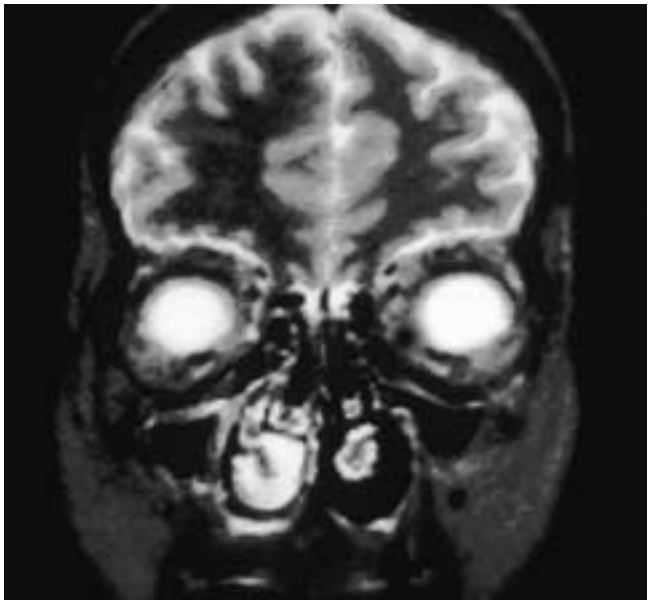
FIGURE 5-28 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show both maxillary sinuses filled with nonhomogeneous signal intensities. In **A**, the majority of the sinus content has a low to intermediate signal intensity, while in **B**, it has a high signal intensity. This represents heaped-up, inflamed mucosa and is the characteristic MR imaging appearance of inflammation. The areas of higher signal intensity in **A** and lower signal intensity in **B** are sites of desiccated secretions. This patient had chronic sinusitis.

resolve any issue.[88] On postcontrast CT and MR images, the turbinates will enhance whether enlarged physiologically or pathologically. On MR images they have low T1-weighted and high T2-weighted signal intensities (Fig. 5-29). Nasal turbinate swelling may also represent an allergy to contrast material on postcontrast CT scans. This is easily confirmed if the turbinates are normal on the initial noncontrast scan.[89]

Polyps and Cysts

The intrasinus polyp and the retention cyst cannot be differentiated on either plain films or sectional imaging. However, this is of little consequence, as both are common benign entities and any treatment is the same.

On all imaging, retention cysts and polyps are homogeneous soft-tissue masses with smooth, outwardly convex borders (Figs. 5-30 to 5-39). Multiple or single lesions may be present; most are small and clearly do not fill the entire sinus cavity. If a cyst or polyp occurs in the roof of the maxillary sinus in a patient with a history of recent trauma, the plain film examination may simulate a blowout fracture (Fig. 5-31). However, coronal CT or MR imaging will



VIEW IMAGE

FIGURE 5-31 Waters view shows a retention cyst or polyp (*arrow*) in the roof of the left maxillary sinus. If there was a history of recent orbital trauma, this could be mistaken for part of a blow-out fracture. In this patient, coronal sectional images would have demonstrated an intact orbital floor.

demonstrate an intact orbital floor, with the cyst or polyp in the antral mucosa.

On the Waters view, a prominent infraorbital canal may mimic a cyst or polyp in the roof of the antrum. Similarly the nasal alae can simulate a medial wall antral cyst or polyp, and unerupted teeth, the lips, or a mustache can simulate a cyst or polyp on the floor of the maxillary sinus. The coronoid process of the mandible can simulate a cyst or polyp in the posterior floor of the antrum on a lateral plain film taken with the patient's mouth closed.

As a cyst or polyp enlarges to fill at least half of the antrum, it behaves like a water-filled thin balloon, the upper surface flattens out, and it resembles an air-fluid level (Fig. 5-40). A true air-fluid level is a fluid level throughout the entire involved sinus, with a concave upward meniscus at the margins of the fluid. Additionally the planar surface of the fluid will directly reflect gravity in every head position. On MR imaging these cysts or polyps usually have characteristics similar to those of mucosal inflammation, again reflecting the high water and low specific protein content. Thus, they tend to have low to intermediate T1-weighted and high T2-weighted signal intensities. If the protein content of the cyst or polyp fluid increases, either due to infection or the passage of time, the T1-weighted signal intensity may become high, reflecting the shortening of the T1 relaxation time.

Retention cysts and polyps are usually asymptomatic and are incidental radiographic findings. However, if they enlarge to fill the entire sinus, they may obstruct sinus drainage and become symptomatic. Rarely, these lesions can remodel the sinus walls and expand the sinus cavity. But in most cases on sectional imaging, small pockets of remaining sinus air can be identified overlying part of the convex margin of the lesion (Fig. 5-34). This distinguishes such a cyst or polyp from a mucocele, although when the lesion is large, the distinction is of more intellectual interest than clinical significance.

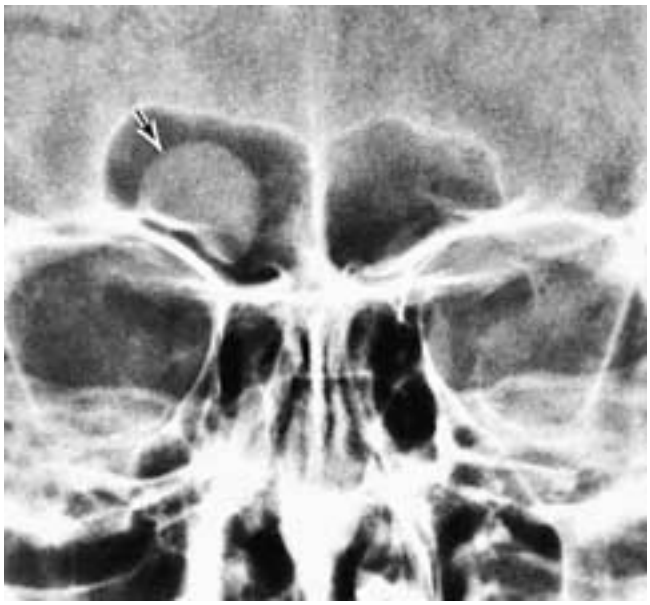

FIGURE 5-32 Caldwell view shows a retention cyst (*arrow*) in the right frontal sinus. Note that this sinus is otherwise normal.

VIEW IMAGE

On sectional imaging, a typical antrochoanal polyp appears as a soft-tissue polyp that completely fills a maxillary sinus. Usually the infundibular region is widened, and there is a slight extrusion of the antral mass into the middle meatus. Alternatively, the polyp can extend through a secondary sinus ostium. At this stage, such an antrochoanal polyp can be confused with hypertrophic polypoid antral mucosa that has also extended through the sinus ostium. However, as the polyp grows, it fills the ipsilateral nasal fossa and extends back into the nasopharynx (Figs. 5-41 to 5-44). It may become sufficiently large to hang down into the oropharynx. Although the medial antral wall may eventually be deossified or destroyed, the remaining antral walls are rarely remodeled. This can be a difficult

diagnosis on plain films, but it is rarely misdiagnosed on sectional imaging. Histologically, antrochoanal polyps differ from inflammatory polyps in that they are fibrotic, with minimal inflammation. The normal minor salivary tissue is obliterated. Of note, atypical fibroblasts may be seen within the lesion, mimicking a neoplastic process. Thus the radiologist may assist the pathologist in ruling out neoplasm by confirming a benign, slowly growing lesion.

On plain films, nasal polyps are often seen as a vague increased soft-tissue density within the nasal fossa. However, on sectional imaging they usually can be identified as discrete single or multiple broad-based soft-tissue masses (Figs. 5-45 to 5-59). On CT, more recent polyps tend to have a mucoid attenuation (10 to 18 HU), with mucosal enhancement occasionally seen at the polyp's surface. However, those polyps that have had sufficient time to develop stromal fibrosis plus desiccation of the secretions tend to have higher overall attenuation (20 to 35 HU). On MR imaging, typically the dominant feature is the high water and low protein content that gives the polyps low to intermediate T1-weighted and high T2-weighted signal intensities. When multiple polyps are present, often intermixed with mucoceles, the

entrapped secretions usually have variable T1-weighted and T2-weighted signal intensities (Figs. 5-56 and 5-57). It is this variable imaging appearance that distinguishes such polypoid masses from tumors, which tend to have more homogeneous signal intensities.[83, 90, 91]

On CT, when there are multiple polyps crowded within the nasal vault, they can form an overall conglomerate mass that may be difficult if not impossible to distinguish from a tumor. This is especially true of bulky lesions such as inverting papillomas and lymphomas that tend to remodel the surrounding bone. However, two findings typical of sinonasal polyps can reliably establish their diagnosis on CT studies. First, an ethmoid polypoid mucocele that involves

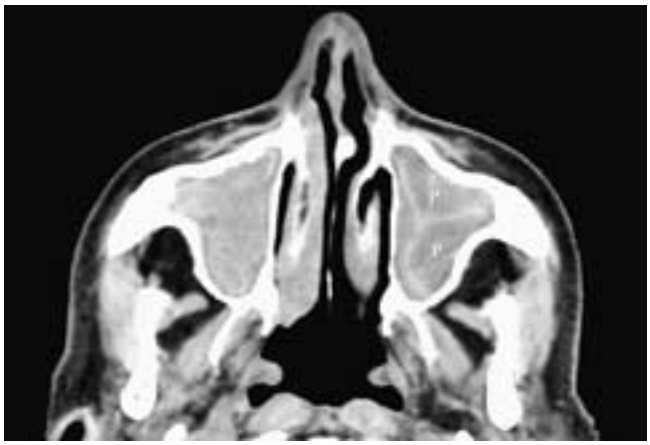

FIGURE 5-37 Axial CT scan shows both maxillary sinuses to be filled. On the right side, there is higher-attenuation material centrally within the sinus cavity representing desiccated secretions. However, on the left side, desiccated secretions form a thin curvilinear zone of higher attenuation, outlining the mucosal polyps (*P*) in this sinus.

VIEW IMAGE

the ethmoid labyrinth unilaterally or bilaterally is characterized by widening of the ethmoid complex, with little if any destruction of the delicate ethmoid septa.[74, 92] The individual ethmoid cells are filled with polypoid mucosa and entrapped mucoid secretions. The CT appearance of each sinus cavity is that of a central high-attenuation region (desiccated secretions) separated from the bony sinus wall by a thin zone of lower mucoid attenuation. By comparison, a solid mass (either a single polyp, a mucocele, or a tumor) will destroy these septa, and in this latter circumstance it is impossible to distinguish a benign lesion from a low-grade malignant process. The preservation of ethmoidal septa, as seen in polypoid mucoceles, unequivocally signifies the presence of benign disease (Figs. 5-52 and 5-53).

Secondly, the finding of a unilateral or bilateral expansile sinonasal mass with cascading, looping, or curvilinear areas of fairly high attenuation (desiccated secretions) in a background matrix of mucoid attenuation (10 to 18 HU) is specific on CT for the presence of a benign process. Usually, these polypoid masses are separated from the adjacent bones by a thin zone of mucoid material (Figs. 5-50 to 5-53). This

However, in **B**, the image is through the midsinus, and a convex margin is seen identifying this high signal intensity retention cyst or polyp. Because large cysts or polyps are essentially fluid-filled bags, gravity can flatten portions of large lesions to simulate an air-fluid level.

unique CT appearance is seen in about 20% of patients with nasal polypoid masses.

On MR, the signal intensity is determined by the degree of desiccation of the secretions entrapped within the sinuses and between and within the polyps. The resulting variable appearance of signal intensities is diagnostic of inflammatory disease. The primary diagnostic problem arises when semisolid or completely desiccated secretions are present. These dried secretions give signal voids on T2-weighted images and, depending on the degree of desiccation, either low signal intensity or signal voids on T1-weighted images. Possible confusion with an aerated sinus can occur unless a CT study is available for comparison (Figs. 5-18 and 5-19).

Sinonasal mucosa adjacent to polyps will enhance on MR imaging, while secretions and fluid within and around the polyps will not enhance. This appearance is distinctive from that of a neoplasm, which enhances more uniformly.

The CT finding of a high-attenuation central region separated from the sinus wall by a thin zone of mucoid attenuation material can be seen in three distinct cases in order of likelihood: chronic inspissated (desiccated) secretions, a mycetoma (usually from aspergillosis), and intrasinus hemorrhage (Figs. 5-8A and 5-60).[93] Although a specific diagnosis may not always be possible on CT, this appearance reliably indicates that the soft-tissue mass is not a tumor.[57] The MR imaging finding of a central intrasinus region of signal void or low T1-weighted and T2-weighted signal intensity can represent either desiccated secretions in chronic sinusitis, a mycetoma in a patient with sinus fungal disease, a sinolith, or an intrasinus tooth (antrum) (Figs. 5-18, 5-19, and 5-61 to 5-66).

The mycetomas are semisolid and have paramagnetic ions, both contributing to their low signal intensity or signal voids on all imaging sequences. Any inflammatory reaction around the mycetoma will have the typical MR imaging characteristics of infections or polyps.[94]

VIEW IMAGE

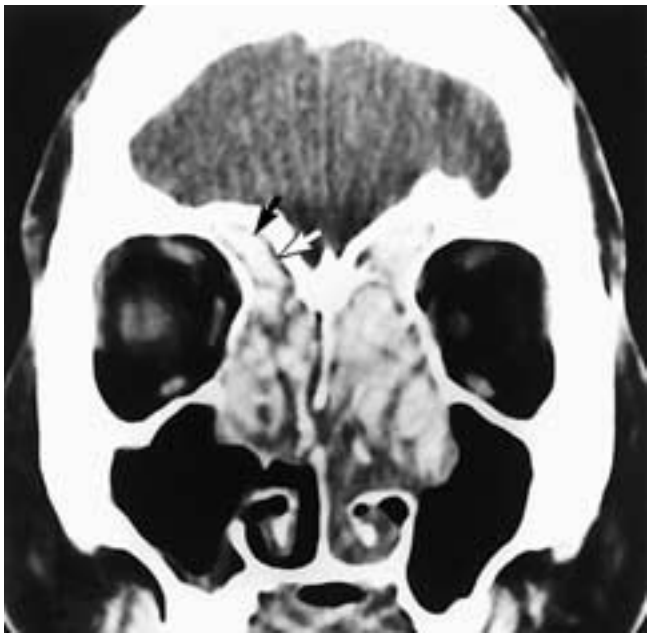
FIGURE 5-49 Axial contrast-enhanced CT scan shows an enhancing left nasal fossa polypoid mass. There are mucosal enhancement and secretions in the left maxillary sinus and mucoid secretions in the right maxillary sinus. This patient had nasal polyps and sinusitis.

An intrasinus hemorrhage initially has a low signal intensity on all imaging sequences. However, when the blood becomes oxidized to methemoglobin (by 24 to 48 hours after the trauma), it has a high T1-weighted and an intermediate T2-weighted signal intensity. Thus, with MR imaging, intrasinus hemorrhage can be distinguished in almost all cases from desiccated secretions and a mycetoma (Fig. 5-8).[17, 18] It should be noted that as long as some air remains in the sinus, it is rare to have any entrapped secretion desiccate enough to have high T1-weighted signal intensity.

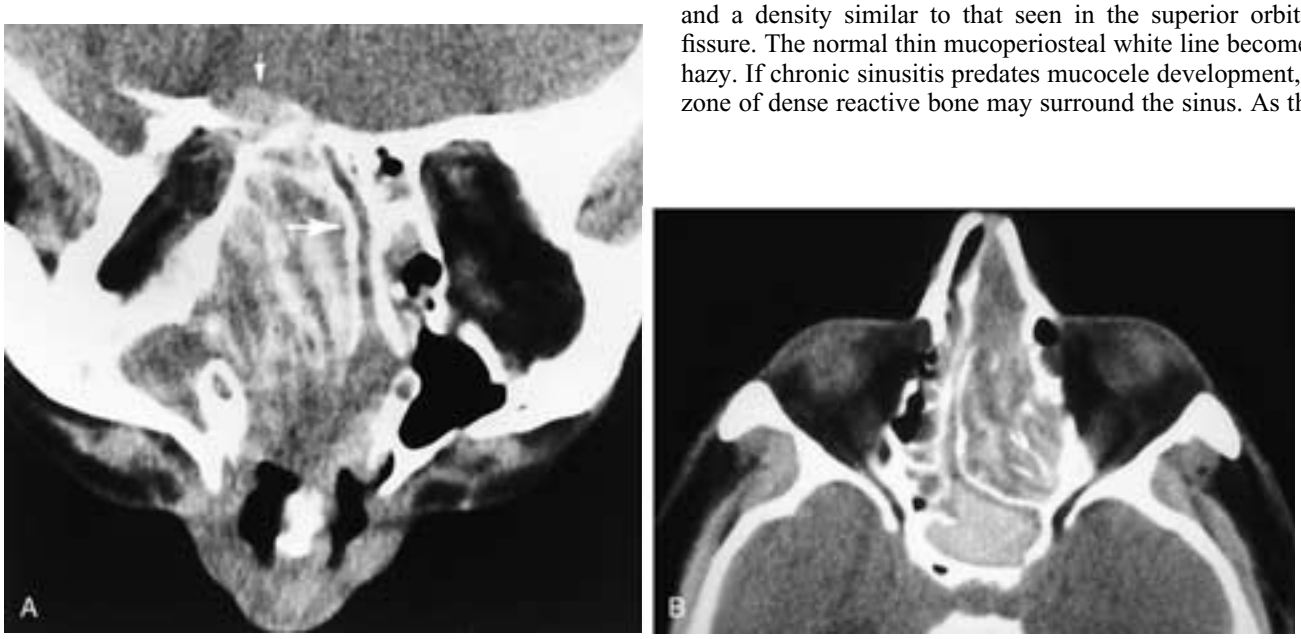


VIEW IMAGE

FIGURE 5-50 Coronal CT scan shows multiple high-attenuation soft-tissue masses extending from the ethmoid sinuses into the nasal fossae. Each polypoid mass is separated from the adjacent bone by a thin zone of mucoid attenuation material (*arrows*). The polyps are also embedded within a matrix of mucoid secretions. This patient had nasal and paranasal sinus polyposis.

Mucoceles

On plain films a frontal sinus mucocele first appears as a slightly clouded sinus with a smooth, ovoid, or rounded contour, in contrast to the normal frontal sinus, which has a scalloped contour with septation extending into the sinus and a density similar to that seen in the superior orbital fissure. The normal thin mucoperiosteal white line becomes hazy. If chronic sinusitis predates mucocele development, a zone of dense reactive bone may surround the sinus. As the



VIEW IMAGE

FIGURE 5-52 Axial (**A**) and coronal (**B**) CT scans show an expansile ethmoid complex mass that has remodeled the thin lamina papyracea laterally. The ethmoid sinuses are filled with high-attenuation material that is separated from the adjacent bone by a thin zone of mucoid attenuation. The sphenoid sinuses are also filled with dense material; however, the sphenoid sinus walls are deossified and appear destroyed. This patient had paranasal sinus polyposis. This case illustrates how the central facial bones can remodel in response to chronic pressure, while the central skull bones primarily deossify. **C**, Axial CT scan on another patient who had had a prior right external ethmoidectomy. Now the CT scan shows an opacified sphenoid sinus with apparent erosion of the skull base along the right side of the sinus. Axial T2-weighted MR image (**D**) shows high signal intensity in the inflammatory sphenoid sinus mucosa and no erosion of the adjacent skull base. This area of the skull base demonstrates pressure deossification from the mucocele. The dried sinus secretions seen in **C** have a signal void in **D** that could easily be overlooked if only MR was available.

mucocele erodes the sinus contour in the vertical plate of the frontal bone, it also slowly erodes the anterior and posterior frontal sinus tables. This results in a loss of bone density on frontal plain films that more than compensates for the soft-tissue density of the mucoid secretions. Thus a frontal sinus mucocele tends to maintain a radiodensity that is equal to or slightly less than that of the adjacent normal frontal bone. If one observes an expansile frontal sinus mass that is denser than the adjacent frontal bone, a fibroosseous lesion is a more likely diagnosis than a mucocele. As a frontal sinus mucocle enlarges, it tends to displace the superior-medial orbital margin downward and laterally, correspondingly displacing the eye (Figs. 5-67 to 5-70). A radiolucent frontal sinus mucocele is seen only when it becomes so large as to erode most of the sinus tables (Figs. 5-70 and 5-71).

A hypoplastic frontal sinus on plain films has a single, smooth, centrally concave border that may simulate a mucocele. The normally scalloped margins of larger sinuses are not present for assessment of possible erosion. However, regardless of the sinus capacity, the boundaries of a normal frontal sinus never violate the orbital contour. Any downward and outward displacement of the superomedial orbital rim (and a similar displacement of the eye) should be considered presumptive evidence of a frontal sinus mucocele until proved otherwise. Similarly the base of the frontal intersinus septum is normally in the midline, and any displacement of this portion of the septum to one side is also suggestive of a frontal sinus mucocele.

The midline segments of the anterior and posterior frontal sinus tables are seen on lateral plain films. Plain films are insensitive in detecting erosion of these tables off of the midline. It is important for the surgeon to know, prior to surgery, whether the posterior frontal sinus wall is intact. Sectional imaging of a suspected frontal sinus mucocele is then mandatory, and asymptomatic intracranial mucocele extention thus can be fortuitously discovered.

Mucoceles can extend posteriorly into the horizontal plate (orbital roof) of the frontal bone, as well as up into the vertical plate. Once in the orbital roof, a mucocele can extend both cranially into the floor of the anterior cranial

fossa and caudally. If this orbital roof extension is not appreciated at the time of surgery, which is usually performed extracranially for the more obvious vertical plate disease, complications from an orbital roof mucocele may require a second operation and an intracranial approach. In the event that frontal sinus surgery was performed without preoperative sectional imaging, and retrospectively the plain films suggest the presence of horizontal recess disease, then postoperative CT or MR imaging is necessary to resolve this issue and provide an important prospective baseline study.

Ethmoid mucoceles usually arise from the anterior rather than the posterior ethmoid cells, presumably because the anterior ethmoid ostia are the smallest of any in the paranasal sinuses.[95, 96] Mucous viscosity also promotes mucoceles, as ethmoid mucoceles are common in patients with cystic fibrosis.[97] Ethmoid mucoceles are typically expansile, thinning and remodeling the lamina papyracea and bowing it laterally into the orbit, resulting in a laterally displaced globe. This may be very difficult to diagnose on plain films despite clinical evidence of a mass. The obliquely oriented lamina papyracea is not well seen on frontal films, and the air density of normal ethmoid cells surrounding the mucocele can partially nullify the soft-tissue density of the mucocele. An air-fluid level in the ethmoid complex can indicate an ethmoid mucocele rupture, with partial drainage into the nasal cavity and adjacent ethmoids. In these cases, a mucopyocele is usually present at the time of discovery (Fig. 5-11).[98]

Mucoceles also can arise in supraorbital ethmoid cells; these are best demonstrated on Caldwell films or coronal images. Infection or a polyp in the lower portion of the supraorbital cell can be the cause of obstruction that leads to these mucoceles, which typically erode through the middle third of the orbital roof and displace the globe inferiorly.

Polypoid mucoceles may involve the entire ethmoid complex, either unilaterally or bilaterally. Characteristically, sectional imaging confirms that ethmoid septa are preserved within the opacified, expanded ethmoid complex. The plain film findings may be only diffuse opacification of the ethmoid complex.

The typical antral mucocele totally opacifies the maxillary sinus and expands the sinus cavity (Fig. 5-72). Unchecked antral mucoceles may eventually overtake the osteoblastic ability of the outer maxillary periostium, resulting in frank bone destruction, thus making the distinction from neoplasia difficult on plain films (Fig. 5-73). If the orbital floor is elevated, the patient may experience diplopia. Rarely, if the mucocele spontaneously collapses after thinning the orbital floor, the globe may descend, causing enophthalmos and diplopia. If the antrum has been compartmentalized by a septum, a mucocele may be limited to only one of these sinus sections. Obviously,

FIGURE 5-66 Coronal T1-weighted (**A**) and axial T2-weighted (**B**) MR images show a slightly expanded right maxillary sinus filled for the most part with inflammatory-type material. Within the sinus is an area of signal void. This could have been residual sinus air, desiccated secretions, a mycetoma, or a sinolith. An axial CT scan (**C**) shows that it was a tooth in a dentigerous cyst. A sagittal T2-weighted (**D**) image on another patient shows an area of signal void (*arrow*) just under the floor of the maxillary sinus. This patient had an undescended molar tooth.

there are significant clinical implications of an unexplored posterior compartmental mucocele. In such cases, the radiologist may be the only physician to detect this hidden mucocele and direct the surgeon to it (Fig. 5-74).[99]

Sphenoid sinus mucoceles have the highest incidence of surgical complication of all mucoceles. Due to their proximity to the optic nerve, blindness is the most serious major postoperative complication. Most sphenoid mucoceles expand anterolaterally into the posterior ethmoids and the orbital apex. Less commonly, expansion may occur upward into the sella turcica and cavernous sinuses or downward into the nasopharynx and posterior nares. In rare cases, intracranial extension can even result in areas of brain necrosis.[100, 101] Occasionally they may extend into the sphenoid sinus recesses in the greater wings and the pterygoid processes.[102] If sufficiently large, sphenoid sinus mucoceles may cause optic canal and orbital apex syndromes. The critical role of the radiologist is to accurately localize the relationship of the optic nerve to the mass, thereby guiding the surgeon during surgical decompression.

Multiple paranasal sinus mucoceles have been reported after facial fractures and in patients with severe allergies. Patients with aspirin intolerance seem to be particularly prone to develop multiple aggressive mucoceles that may extend intracranially.[103]

The finding on CT of an expanded, airless sinus cavity filled with fairly homogeneous mucoid attenuation (10 to 18 HU) secretions is diagnostic of a mucocle.[104] However, if the entrapped secretions are particularly viscid and proteinaceous, the attenuation can increase to 20 to 45 HU, similar to that of muscle. If the sinus is airless, filled with a mucoid density but not expanded, the diagnosis is that of an obstructed sinus, not a mucocele (Figs. 5-75 and 5-76). When a mucocele is present, the sinus walls are remodeled and may be of almost normal thickness, thinned, or partially eroded (Figs. 5-77 to 5-90). In the latter two cases, the sinus

VIEW IMAGE

mucosa and the sinus wall periostium are all that surround the mucous secretions. If a mucopyocele is present, the inflamed sinus mucosa is seen as a thin line of enhancement just inside the bony sinus walls, establishing the diagnosis of an infected mucocele (Fig. 5-91).[32]

Prior Caldwell-Luc procedures may result in a fibrous septum between the lateral margin of the anterior sinus wall surgical defect and the posterior sinus wall. Synechiae can form and organize into a solid fibrous wall. The resulting septum can obstruct the drainage from the lateral portion of the sinus, while the sinus cavity medial to the septum drains normally. Thus an expansile mass in the lateral maxillary sinus is diagnostic of this condition. As it enlarges, a lateral antral mucocele may extend into the body of the zygoma and present in the cheek as a soft-tissue mass or it may extend into the lateral, inferior orbit (Figs. 5-92 and 5-93).

On MR imaging, the signal intensities of a mucocele are determined by the protein content of the entrapped secretions. As previously discussed, secretions become more con-

VIEW IMAGE

VIEW IMAGE

FIGURE 5-71 Caldwell view shows a smoothly contoured, enlarged frontal sinus. There is a surrounding zone of sclerosis, and only the most lateral portion of the left frontal sinus appears normal. There is erosion of the right superior and superomedial orbital rim, and a mound of soft tissue is seen above the mass (*arrows*). This patient had a frontal sinus mucocele that caused the forehead to bulge and resulted in right proptosis.

centrated and viscous over time and the T1-weighted and T2-weighted signal intensities vary. The relaxation-time shortening can be used to approximate the viscosity of the secretions, as shown in Figure 5-17 (Figs. 5-94 to 5-101).[83] On contrast-enhanced MR images, the sinus mucosa enhances and is seen as a uniformly thin zone surrounding the nonenhancing secretions. If a mucopyocele is present, the infection causes increased viscosity of the secretions, shorter relaxation times, and thickening of the mucosa.

If there is a mucoid collection in the antrum and a double bony wall is seen in the maxillary sinus, often at the most anterior or posterior margin of the sinus, it implies that the bony floor has been elevated by an odontogenic process (Fig. 5-102). This is important to recognize, as the surgical treatment of an odontogenic cyst differs from that of an antral mucocele.

VIEW IMAGE

VIEW IMAGE

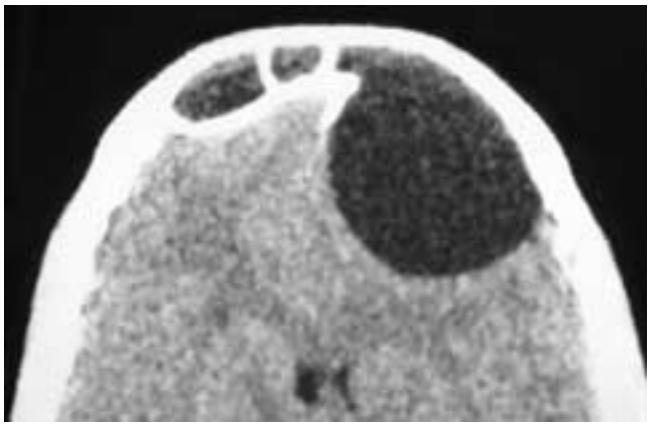
FIGURE 5-75 Axial CT scan shows an opacified right maxillary sinus. The attenuation of the material is approximately that of water. The sinus cavity is normal in size. This is an obstructed sinus, not a mucocele. In a mucocele, the sinus cavity must be enlarged.



VIEW IMAGE

FIGURE 5-77 Axial CT scan shows a large, expansile mucoid attenuation mass in the left frontal sinus that has thinned the posterior sinus table and bulged intracranially. A smaller mucocele that extended down into the orbit is also present on the right side. The left mucocele contents are separated from the brain by sinus mucosa, deossified bone, and the meninges. This patient had bilateral frontal sinus mucoceles.

Fungal Diseases

Mycotic sinusitis has a highly variable appearance. During early infection, merely nonspecific mucosal inflammation in the nasal fossa or paranasal sinus(es) is seen.[105, 106] Most often either the maxillary sinus or ethmoid sinuses are involved. The sphenoid and frontal sinuses are only occasionally affected.[107] Air-fluid levels are uncommon and, when present, suggest a bacterial infection. The surrounding bone in mycotic sinusitis may be thickened and sclerotic, eroded, or remodeled. Most often it is the combination of these bone changes that suggests either an unusual infection or fungal disease.[108]

Soft-tissue disease is often found both in the nasal fossa and the paranasal sinuses. In antral mycotic sinusitis, the nasal disease may act as a bridge for extension of infection into the cheek. This finding suggests an aggressive infection or fungal disease, as antral bacterial sinusitis rarely

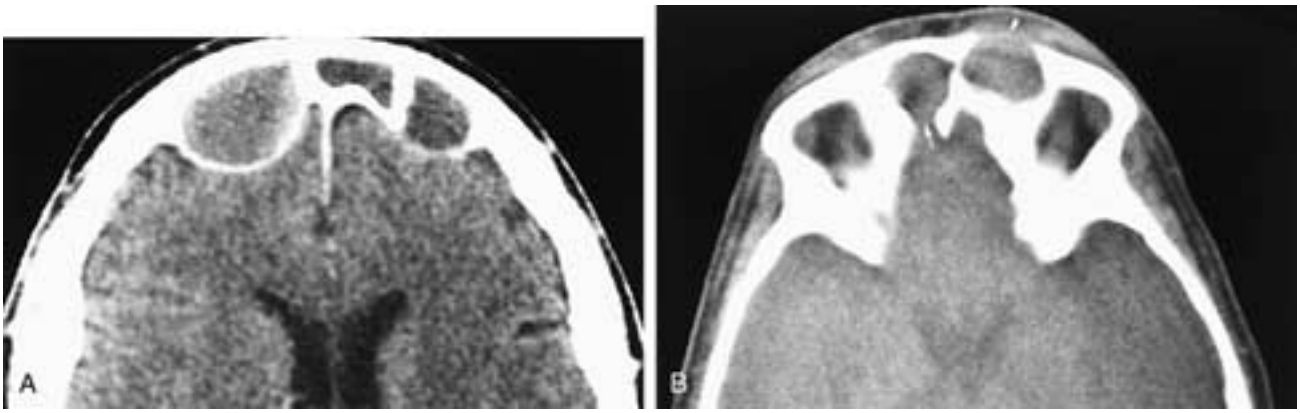
extends into the facial soft tissues.[109] Intrasinus concretions within a mycetoma can be seen occasionally on plain films and CT (Figs. 5-103 to 5-105).[110, 111] As previously discussed, the signal void and adjacent sinus inflammation of a mycetoma mimic the MR imaging appearance of nonspecific chronic infection with desiccated secretions (Figs. 5-61 to 5-65).

INFECTIOUS DESTRUCTIVE AND GRANULOMATOUS SINONASAL DISEASES

Actinomyces and *Nocardia*

Actinomycosis is a commensural organism of human and bovine hosts; unlike most true fungi, they have not been identified as environmental saprophobes. The human pathogen, *Actinomyces israelii* (and, less often, *A. eriksonii*) is normally present around teeth, especially carious teeth, and in tonsillar crypts. It is classified as a filamentous bacterium rather than a fungus because (1) it reproduces by fission rather than by sporulation (as do perfect fungi) or filamentous budding (as do imperfect fungi), and (2) muramic acid is present in its cell walls and mitochondria are absent, both of which are features of bacteria.

Actinomyces has limited pathologic potential in the normal host. Antecedent trauma or other precursors are necessary predisposing factors for invasive infection. There are three forms: cervicofacial, thoracic, and abdominal; the cervicofacial is the most common form of infection. Soft-tissue abscesses and draining cervical fistulae develop as a result of secondary *Actinomyces* infection of periapical abscesses. Actinomycosis can also present in the neck without the characteristic sinus tracts. These sinuses can occasionally have long tracts, communicating with the soft tissues of the back and chest. Aspiration of oral *Actinomycetes* from carious teeth may lead to pulmonary abscess formation and pneumonia. Rarely, *Actinomyces* may be the cause of sinonasal, laryngeal, or pharyngeal disease.



VIEW IMAGE

FIGURE 5-80 Axial CT scan (**A**) shows bilateral frontal sinus expansile masses. Each mass has thinned and remodeled the posterior sinus wall, and each mucocele bulges intracranially. On the plain film, the posterior sinus wall appeared intact. This patient had bilateral frontal sinus mucoceles. Axial CT scan (**B**) on another patient shows an expansile mass in each of the left and right frontal sinuses. The left-sided mass has broken through the anterior sinus wall (*arrowhead*), and the right-sided mass has broken through the posterior sinus wall (*arrow*). This patient had bilateral frontal sinus mucoceles.

The pale yellow ''sulfur granules'' or ''grains'' observed clinically are microcolonies of bacilli. On hematoxylin and eosin (H&E) stain, only blue amorphous masses are visible. The slender, filamentous nature of these bacilli is apparent on special stains. The filaments may mimic fungi in their tendency to branch. *Actinomycetes* are routinely not acid-fast, although occasionally they may be weakly acid-fast. This point can help distinguish *Actinomyces* on tissue sections from *Nocardia*. The latter filamentous

bacterium does not stain well with H&E but does stain well with a modified Ziehl-Neelson stain. The distinction between these two filamentous bacteria is important because their sensitivity to antibiotics differs; penicillin is the drug of choice for *Actinomyces*, but *Nocardia* (most human infection is caused by *N. asteroides*) is unresponsive to penicillin and can be treated with sulfa drugs. The diagnosis of actinomycosis is confirmed by an aerobic culture.[34, 112–114]

Tuberculosis (TB) is caused by *Mycobacterium tuberculosis* and *M. bovis*, aerobic bacilli with a thick, multilayered capsule of complex lipids and waxes, which accounts for their staining and immunogenic properties. Once stained, they are resistant to decolorization by acid alcohol and hence are acid-fast. The disease has a worldwide distribution. *M. tuberculosis* is spread through aerosolized respiratory droplets from patients with cavitary TB. *M. bovis* and probably *M. tuberculosis* can cause infection via oral ingestion, although mucosal breaks are probably required. A definite resurgence has been reported in the United States as a result of (1) immigrant populations from endemic countries, (2) reactivation of disease in the elderly population, and (3) the AIDS pandemic. More than 25,000 cases were reported in the United States in 1993 (10 cases per

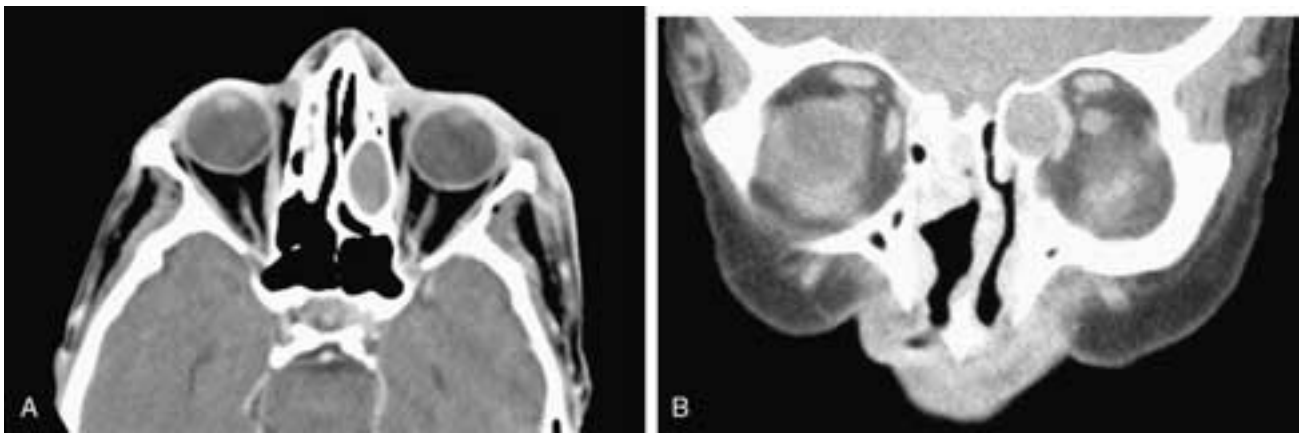
100,000 people), a 14% increase over reported rates in 1985, which were at a nadir since national reporting began in 1953.[115] The common tuberculous pulmonary disease may be asymptomatic or cause fever, weight loss, and bloody sputum. Head and neck involvement in TB is rare and is thought to be the result of direct infection from expectorated sputum, as well as from hematogenous-lymphatic spread. The sinus disease may be nonspecific; however, when bone involvement occurs, the dominant symptom is pain. The treatment is prolonged antituberculous chemotherapy. Nasopharyngeal and sinonasal TB may clinically and histologically mimic Wegener's granulomatosis. This distinction has a grave consequence because administering the steroid and immunosuppressive agents indicated for active Wegener's granulomatosis may result in miliary progression of unrecognized TB. Also, nasopharyngeal TB can be accompanied by lymphadenopathy. This may clinically mimic nasopharyngeal carcinoma, especially in the Asian population at risk for this neoplasm.[116]

Syphilis is a worldwide disease that has been rising in incidence since the 1980s.[117] In 1977, the rate per 100,000 people in the United States was 10.4. The rate per 100,000 has been between 40 and 60 from 1988 to 1992, and more than 110,000 cases were reported in the United States in 1992. Changing patterns of sexual promiscuity and prostitution have led to the disease resurgence. Syphilis is caused by *Treponema pallidum*, which is usually transmitted through sexual relations, although it can also be transmitted through blood transfusions. By contrast, *T. pertenue* is transmitted through nonvenereal, direct contact.

Syphilis may be divided clinically into three distinct phases: primary, secondary, and tertiary. The first two stages may escape clinical notice. Primary acquired syphilis develops within 1 week to 3 months following exposure. A characteristic chancre develops at the site of infection. Chancres can also develop after orogenital contact. Oral sites include the lips, palate, gingiva, tongue, and tonsil. Chancre has also been reported in the nose.[34, 118] Secondary syphilis occurs weeks to months after the primary chancre and is the result of systemic infection. There is a macular-papular rash that coalesces into warm, moist areas to form hyperplastic lesions: condyloma lata or flat condylomata. Head and neck manifestations of secondary syphilis include condyloma lata, which may occur in the larynx, ears, and nasolabial folds. Tertiary syphilis is a late manifestation seen years to decades after primary infection.



VIEW IMAGE

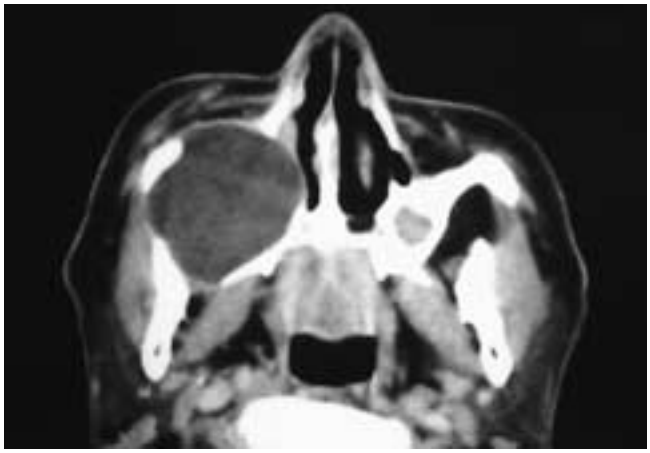
FIGURE 5-89 Axial CT scan shows a water attenuation, expansile mass in the right posterior ethmoid/sphenoid sinus area. The mass displaces the optic nerve and medial rectus muscle downward and laterally. This patient had a sphenoethmoidal mucocele. In these cases, the radiologist must carefully note the position of the optic nerve in relationship to the mass in order to help guide the surgeon away from intraoperative complications.

Ulcerated erosive gummas with indurated margins may develop. The gumma is a destructive, usually painless granulomatous process, which most likely represents a hypersensitivity reaction to *T. pallidum*, as well as progression of the disease to the tertiary phase. Gummas tend to develop in intramembranous bones such as those of the scalp, face, nose, nasal septum, and paranasal sinuses.[34, 118, 119] Without awareness of patient serology, the radiologist should be aware that syphilis can mimic Wegener's granulomatosis or sinonasal fungal disease. Mandibular resorption has been reported and may lead to spontaneous fracture. The treatment of choice remains penicillin.

Congenital syphilis may develop if transplacental infection occurs after the fourth fetal month (when immune competence develops) and within 2 years of the acquired maternal infection. The primary manifestations occur in the mucocutaneous tissues and bones; in the head and neck the



VIEW IMAGE

stigmata include frontal bossing (of Parrot), small maxilla, high palatal arch, Hutchinson's triad (Hutchinson incisors), interstitial keratitis, eighth nerve deafness, saddle nose, and mulberry molars.[34] The spirochete causes a periostitis that interferes with bone development.[120]

The differential diagnosis of syphilis includes yaws (*framboesia tropica*), a nonvenereally transmitted infection caused by *T. pertenue*, which occurs in children and young adults primarily in nongenital, unclothed areas. It is endemic in Central and West Africa and Southeast Asia. Uncommonly the late stages of the disease produce granulomas in the mucous membranes of the sinonasal cavities. These granulomas produce severe ulcerations of the nasal region (gangosa) and proliferative exostoses along the medial wall of the maxillary sinus (goundou). The treatment is penicillin. Histologically the spirochetes of *T. pertenue* tend to be more epidermotropic than those of *T. pallidum*, which can be present mainly at the dermal-epidermal junction and dermis. However, the clinical history is probably most helpful in distinguishing between syphilis and yaws.

Rhinoscleroma, which is caused by *Klebsiella rhinoscleromatis*, a gram-negative bacterium, is an infection that is endemic at tropical latitudes (Central America, Chile, and Central Africa), at subtropical latitudes (India, Indonesia, Egypt, Algeria, and Morroco), in temperate latitudes (Eastern and Central Europe), and in the Russian republics. *K. rhinoscleromatis* is an organism of low infectivity and is not a normal commensal organism. Human-to-human contact is assumed to be the only mode of transmission, and the infection results only after prolonged exposure.

Rhinoscleroma affects the nasal cavity and sinuses; however, it can involve the entire upper respiratory tract, so much so that the general name *scleroma* had been advocated. The natural course of this infection evolves through three stages. The early stage is the atrophic catarrhal stage; the involved mucosa is reddened and atrophic, with a foul purulent discharge and crusting. The clinical differential diagnosis in this early stage includes infection with *Klebsiella ozaenae*. The granulomatous stage may appear, months to years later, as waxy, ulcerating inflammatory masses that distend and deform the mucosal surfaces. The

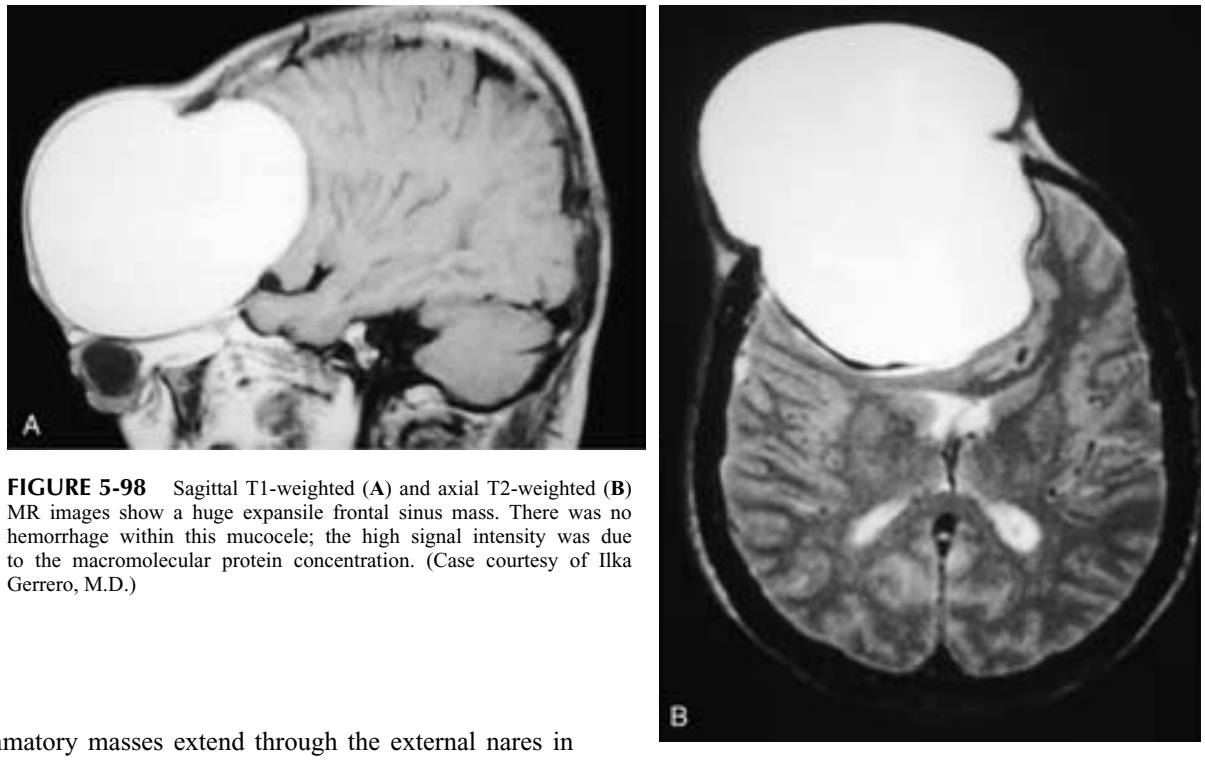

FIGURE 5-98 Sagittal T1-weighted (**A**) and axial T2-weighted (**B**) MR images show a huge expansile frontal sinus mass. There was no hemorrhage within this mucocele; the high signal intensity was due to the macromolecular protein concentration. (Case courtesy of Ilka Gerrero, M.D.)

inflammatory masses extend through the external nares in severe cases and may distort the soft tissues of the midface, resulting in a rhinoceros-like appearance. The clinical differential diagnosis includes leprosy and syphilis. The final sclerotic stage is characterized by fibrosis along with the inflammation, culminating in stenosis.[121]

Rhinosclerosis has been reported in AIDS patients, but the mucocutaneous infections do not appear to differ from those occurring in the usual hosts.[122] The treatment of choice is surgical excision to open the airway and long-term antibiotic therapy, usually with tetracycline.[34]

North American blastomycosis is caused by *Blastomyces dermatitidis*, and the disease is endemic in the Ohio and Mississippi River basins. The disease is not confined to North America and has been detected in South America and Africa. A noted increase in blastomycosis has been seen among avid bird watchers. Based on point source case studies, it appears that closeness between the individual's face and soil (e.g., picking up objects from the ground to examine them) makes one more vulnerable to infection.

Blastomyces may cause disease either through inhalation or through traumatic inoculation into skin. Clinically, blastomycosis may present as the acute onset of pneumonia with fever, productive cough, and myalgias. Patients with insidious infection have symptoms such as weight loss, malaise, anorexia, and a chronic cough that may clinically mimic tuberculosis. Most of the head and neck lesions involve the skin, but involvement of the larynx and nasal

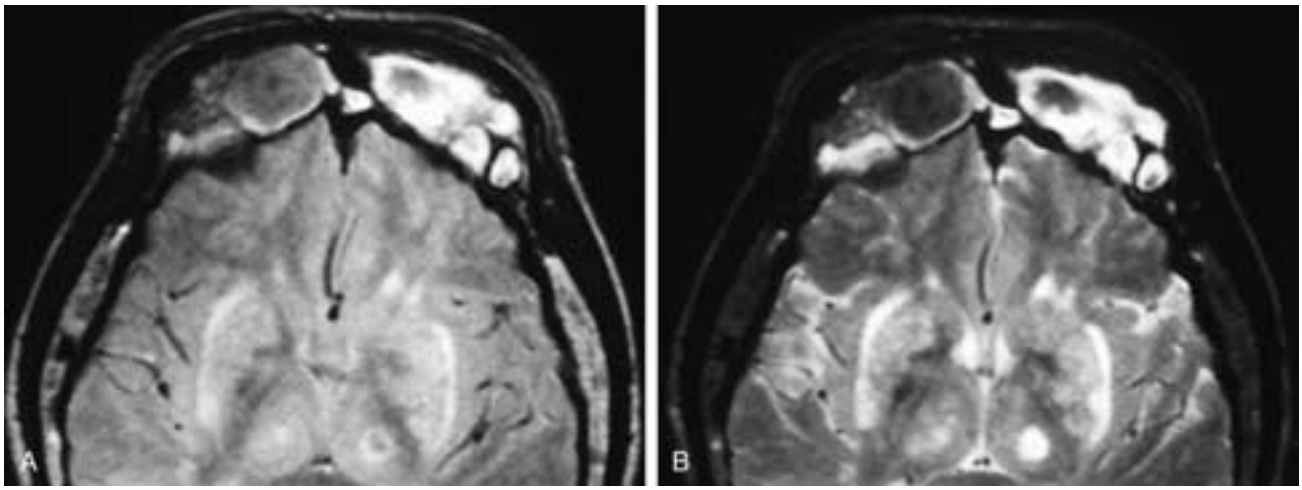

FIGURE 5-99 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show bilateral expansile, nonhomogeneous frontal sinus masses. On the right side, the mass has overall low to intermediate T1-weighted and low T2-weighted signal intensities. On the left side, the mass has an overall high signal intensity on both T1-weighted and T2-weighted images. This patient had bilateral frontal sinus mucoceles.

cavity has been reported. The laryngeal disease may appear clinically identical to carcinoma. Oral lesions may have associated draining sinuses, mimicking actinomycosis. The primary treatment of choice is amphotericin B.[34, 123]

South American blastomycosis (paracoccidioidomycosis) is caused by the dimorphic fungus *Blastomyces brasiliensis*. The disease is endemic to South America, especially Brazil, Colombia, Venezuela, Uruguay, and Argentina. As with coccidioidomycosis, a wide range of disease can be seen, from subclinical to clinical, in immunologically normal patients, patients who are immunosuppressed, and patients with AIDS. Aspiration with subsequent hematogenous dissemination is thought to be the mode of transmission because pulmonary involvement is common. It may produce painful, destructive granulomas of the alveolar process, gingiva, nasal cavity, and, rarely, the paranasal sinuses.[5, 123, 124] The primary treatment is amphotericin B, which cures more than 90% of the cases.[125]

Leprosy is caused by the pleomorphic acid-fast bacterium *Mycobacterium leprae*. The disease occurs in almost all tropical and warm temperate regions, including Latin America, South and Southeast Asia, Saharan Africa, the Mediterranean basin, and Northern Europe. In the United States, endemic states include Florida, Louisiana, Texas, California, and Hawaii. Leprosy affects more than 11 million people worldwide; the number of indigenous cases in the United States has remained stable (10 to 29 per year) over the last two decades. However, the number of imported cases reported in the United States has dramatically increased (up to 300 per year) since the late 1970s. This increase in imported cases did not lead to increased transmission among the U.S. population.

Leprosy is a disease of low infectivity transmitted through prolonged exposure either through nasal secretions or through injured skin. Immunologically, leprosy can be graded by the host response as tuberculoid leprosy (characterized by a robust immunologic response, with few bacilli and with the possibility of spontaneous cure), borderline leprosy, and lepromatous leprosy (characterized by anergy to the lepromin test and abundant bacilli). Clinically there is a widespread, symmetrical facial distribution of lesions lead-

ing to a coarsening of features. The earlobes and nose are especially enlarged and infiltrated. Intranasal and paranasal sinus involvement is common and occurs after cutaneous nasal involvement. The changes in the sinonasal cavities are those of nonspecific chronic sinusitis and rhinitis. Later changes resemble those of a chronic granulomatous disease. A characteristic finding is progressive erosion of the anterior nasal spine. If previous surgery, trauma, and congenital maxillonasal dysplasia are not applicable to the patient, this finding is pathognomonic of leprosy (Fig. 5-106). Retrograde laryngeal involvement usually follows nasal disease. The treatment of choice remains the long-term administration of sulfone derivatives (dapsone).[125]

Rhinosporidiosis is caused by the fungus yeast *Rhinosporidium seeberi*.[126] The disease has a worldwide distribution but is endemic in places like India, Sri Lanka, Malaysia, Brazil, and Argentina. In the United States, cases have been reported in the rural South and West. Preceding mucosal trauma (e.g., by digital contamination or dust storms) is considered necessary in establishing the infection.[127] Patients with rhinosporidiosis generally are otherwise healthy. *Rhinosporidium* most commonly infects the conjunctiva and nasal cavity, with resultant friable, lobulated polyps that may cause obstruction of the nasal fossae and may be confused with neoplasms, especially cylindrical cell papilloma.[34] The nasal polyps are sessile, soft, pinkish, usually unilateral, and they may diminish aeration in the paranasal sinuses. The treatment of choice is surgical excision or electrocautery.

Glanders, or farcy, is caused by the bacterium *Pseudomonas mallei*. It is contracted by contact with horses, mules, or donkeys. In humans the disease is characterized either by an acute fulminant febrile illness that may lead to death or by a chronic indolent granulomatous disease. *Farcy* refers to the nodular abscesses found in the skin, lymphatics, and subcutaneous tissues.[125] The nasal manifestations of glanders are nasal cellulitis and necrosis that produce septal perforations. The treatment is with sulfonamides.

Leishmaniasis causes mucocutaneous infection (*Leishmania tropica*, known as Oriental sore or ''Old World'' sore; *L. mexicana* or *L. brasiliensis*, known as espundia or ''New World'' sore). The disease is endemic to Central and South America. After the initial primary cutaneous sores appear, satellite lesions develop in the nose and mouth; these sores are painful, mutilating erosions that can secondarily involve the sinuses.[125, 128] Scarring may eventually constrict the nose or mouth, producing gross deformities that interfere with swallowing. The majority of the oronasal diseases are caused by *L. brasiliensis*, and the treatment of this established oronasal disease is with amphotericin B.

NONINFECTIOUS DESTRUCTIVE SINONASAL DISEASE

Wegener's granulomatosis is a necrotizing granulomatous vasculitis that usually affects the upper and lower respiratory tracts and causes a renal glomerulonephritis. A limited form of Wegener's granulomatosis may occur, with a more benign course in which only the sinonasal tract is affected. The initial disease may present as a chronic, nonspecific inflammatory process of the nose and sinuses and may remain as such for 1 to 2 years. Usually the nasal septum is first affected. The process becomes diffuse, and septal ulceration and perforations may result in a ''saddle nose'' deformity. Secondary bacterial infections complicate the clinical and imaging pictures.

The diagnosis of Wegener's granulomatosis may be difficult to establish early in the disease course or during periods of inactivity. The radiologist can suggest biopsy of the paranasal sinuses as opposed to the nasal cavity. Although this site is not as readily accessible as the nasal cavity, it has a greater yield of specific diagnostic features that aid the pathologist. Serum antineutrophil cytoplasmic antibodies (ANCA) are elevated during periods of active disease. In the absence of a specific diagnosis of Wegener's granulomatosis, it behooves the pathologist and the clinician to rule out other infectious and malignant causes of destructive sinonasal disease. Wegener's granulomatosis is probably autoimmune in origin, and the treatment of choice is cyclophosphamide, steroids, and possibly other cytotoxic drugs. Long-term remissions have been achieved; however, it is impossible to predict how long a remission will last.[125, 129]

Lethal midline granuloma, which was once classified as a granulomatous disease, was then reclassified as malignant midline reticulosis or polymorphic reticulosis.[129, 130] The disease is now classified as a lymphoma, and it is discussed in Chapter 6.

Sarcoidosis is a systemic, multisystem disease characterized by noncaseating epithelial granulomas.[131–133] An infectious etiology has been sought for these granulomas. Two decades ago, experimental data were presented suggesting the transmissibility of these granulomas, hence fulfilling one of Kock's postulates for an infectious etiology.

VIEW IMAGE

FIGURE 5-107 Axial (**A**) and coronal (**B**) CT scans show destruction of the nasal septum and portions of each medial maxillary sinus wall and the lower ethmoid complex. The distribution of disease suggests a granulomatous process. This patient was a chronic cocaine abuser.

Patients with sarcoidosis have elevated levels of antibodies to *Mycobacterium paratuberculosis*. However, direct inoculation of sarcoid tissue into a thymic mouse has failed to isolate an infectious agent, so at present no known agent has been directly implicated in the etiology of sarcoidosis.

Sarcoidosis has a predilection for the Scandinavian countries and for the rural southeastern United States. It is most common in African-American females with a median age of 25 years. Nasal sarcoidosis occurs in 3% to 20% of the patients with systemic sarcoidosis. When it occurs, there are multiple small granulomas of the nasal septum and turbinates. There may be nasal discharge, obstruction, and epistaxis. Polypoid degeneration of the nasal fossa mucosa may occur, but the paranasal sinuses are rarely affected. Sarcoidosis is not generally a destructive disease in the sinonasal tract; however, destruction of the nasal septum and turbinates can occur in unusual cases. Rarely, sharply defined lytic bone lesions may occur in the calvarium and facial skeleton. Steroid therapy may suppress the inflammatory reaction and provide symptomatic improvement, but fibrous organization of the granulomas may lead to organ dysfunction.[34, 134]

Exposure to beryllium may result in chronic granulomas of the nasal fossa. These granulomas may be indistinguishable from those of tuberculosis, leprosy, and sarcoidosis.[128] Chromate salts have been implicated as a cause of nonspecific granulomas of the nasal cavity; involvement of the paranasal sinuses is a late and unusual event. Cocaine abuse has become a major worldwide problem. Cocaine causes a necrotizing vasculitis and subsequent granuloma of the nasal septum, which with prolonged exposure usually results in septal erosion. Erosion of the nasal vault margins and the adjacent sinuses can occur in chronic abusers. A nonspecific mucosal inflammation may also occur in the nasal fossa. A mucosal reaction to the talc used to ''cut'' the cocaine can also occur.

Imaging

In general, the destructive granulomatous diseases result in variable sinonasal mucosal changes, ranging from nonspecific inflammation with mucosal thickening and nasal secretions to a localized soft-tissue mass. Nasal cavity involvement usually precedes paranasal cavity disease. The nasal septum may be focally thickened by a bulky soft-tissue mass or septal erosion may be present. When the paranasal sinuses are involved, the maxillary and ethmoid sinuses are most often affected. The sphenoid sinuses are uncommonly involved, and the frontal sinuses are almost always spared. When the sinuses are affected, there is usually nonspecific inflammatory mucosal thickening. Air-fluid levels are rare. The bones of the nasal vault and affected paranasal sinuses may be thickened and sclerotic, reflecting the chronic nature of the inflammatory reaction. Sinus obliteration by reactive bone may also occur.[135] Similarly there may be areas of bony erosion, reflecting either osteomyelitis or necrosis. If the nasal disease becomes a bulky soft-tissue mass, there may, in addition, be remodeling of the adjacent bones (Figs. 5-106 to 5-111).[122]

On MR imaging, these diseases may have low T1-weighted and high T2-weighted signal intensities suggestive of an inflammatory disease. They also may have low to inter-

mediate T1-weighted and T2-weighted signal intensities simulating malignancies. They all enhance with contrast.[136] However, not all septal masses represent granulomatous-type disease. In addition to chondroid tumors, a septal abscess can occur, usually following local trauma (Fig. 5-110B,C).

CHOLESTEATOMAS

Several entities in addition to mucoceles can cause sinus cavity enlargement. An epidermoid inclusion cyst (or cholesteatoma) is a cystic keratin-filled mass lined by stratified squamous epithelium. In the frontal bone, these cysts probably arise from a congenital inclusion rest or after traumatic implantation. They may develop either in the diplöe or, less frequently, in the outer table of the skull. On plain films they appear lucent when compared with the adjacent normal frontal bone. The margins may be slightly scalloped or smooth, and there is a thin, uniform white line that identifies the lesion's contour. These latter two findings help differentiate an epidermoid inclusion cyst from a mucocele (Fig. 5-112). Confusion with a mucocele may occur if an epidermoid inclusion cyst arises within or adjacent to the frontal sinus.[137, 138] These cysts may also rarely arise from other flat facial bones.[139]

In the antrum, invasion of buccal epithelium via an oroantral fistula has also been proposed as a possible etiology for an antral epidermoid inclusion cyst. A type of ''cholesteatoma'' or pseudocholesteatoma may develop within a chronically infected sinus after active infection has subsided. The breakdown products of the purulent exudate, as well as any blood, may contain cholesterol products that result in cholesteatomatous debris.[140–142]

An antral epidermoid inclusion cyst must also be differentiated from an odontogenic keratocyst. The latter is a benign cystic neoplasm arising from odontogenic rests that

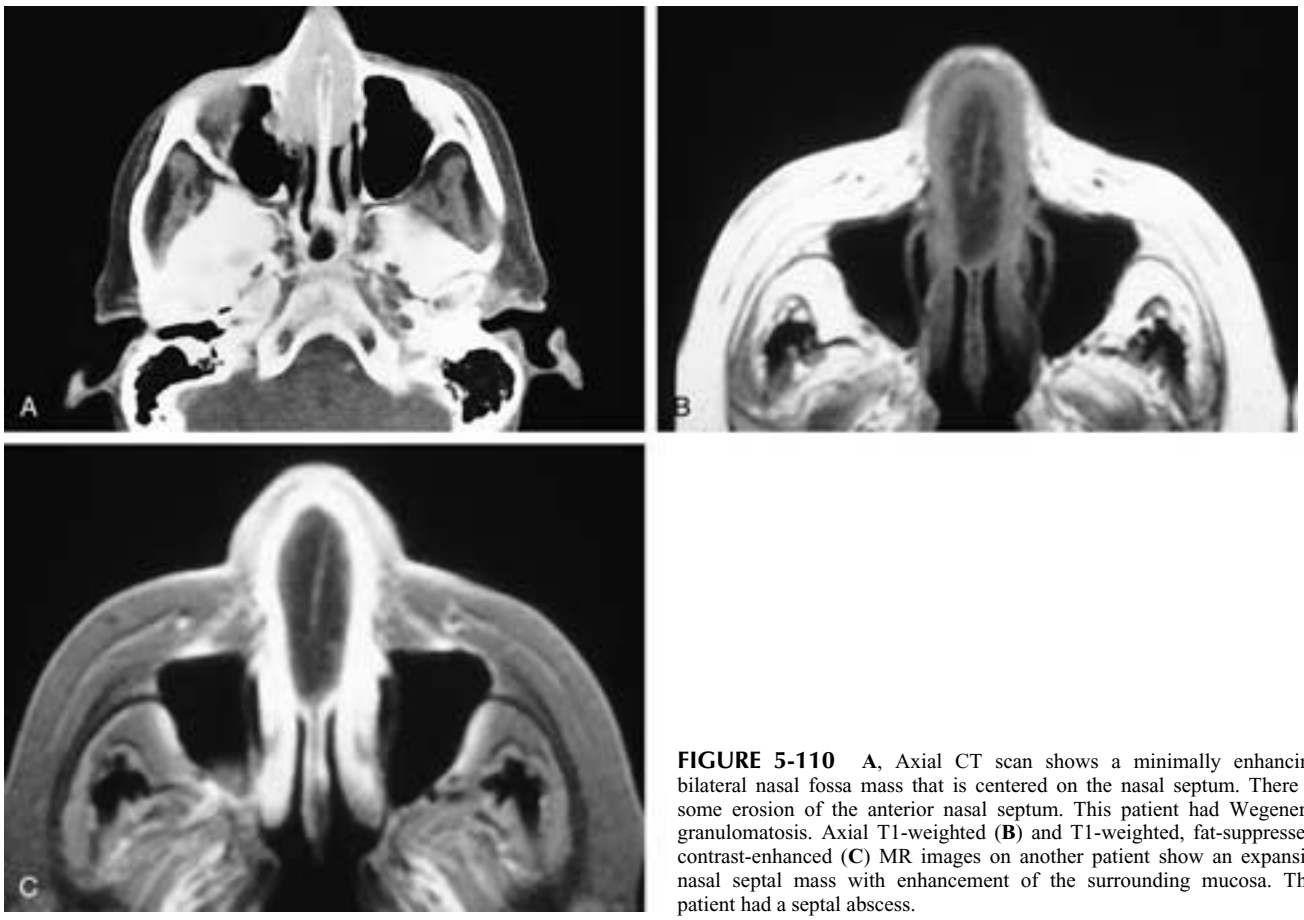

FIGURE 5-110 **A**, Axial CT scan shows a minimally enhancing bilateral nasal fossa mass that is centered on the nasal septum. There is some erosion of the anterior nasal septum. This patient had Wegener's granulomatosis. may also remodel and expand the maxilla (see Chapters 6 and 17).

On CT, an epidermoid inclusion cyst or a cholesteatoma appears as an expansile lesion that has soft tissue, mucoid-like attenuation. If it occurs within a sinus cavity, it may be indistinguishable from a mucocele. On MR imaging, depending on the fatty components of the cholesterol, there can be an intermediate to high signal intensity on T1-weighted images and there usually is an intermediate to high signal intensity on T2-weighted images (Fig. 5-113).[143, 144]

ENLARGED AERATED SINUSES

When evaluating a large sinus, there are no definitive measurements that define abnormal enlargement. Part of the problem is lack of pathologically confirmed etiologies for these processes. In one study, a sinus was judged to be abnormally large if its size exceeded that of 99% of the normal population.[145, 146] Using that criterion and taking into account magnification factors for films taken on a Franklin head unit (3.4%) or a standard 40-inch focal-

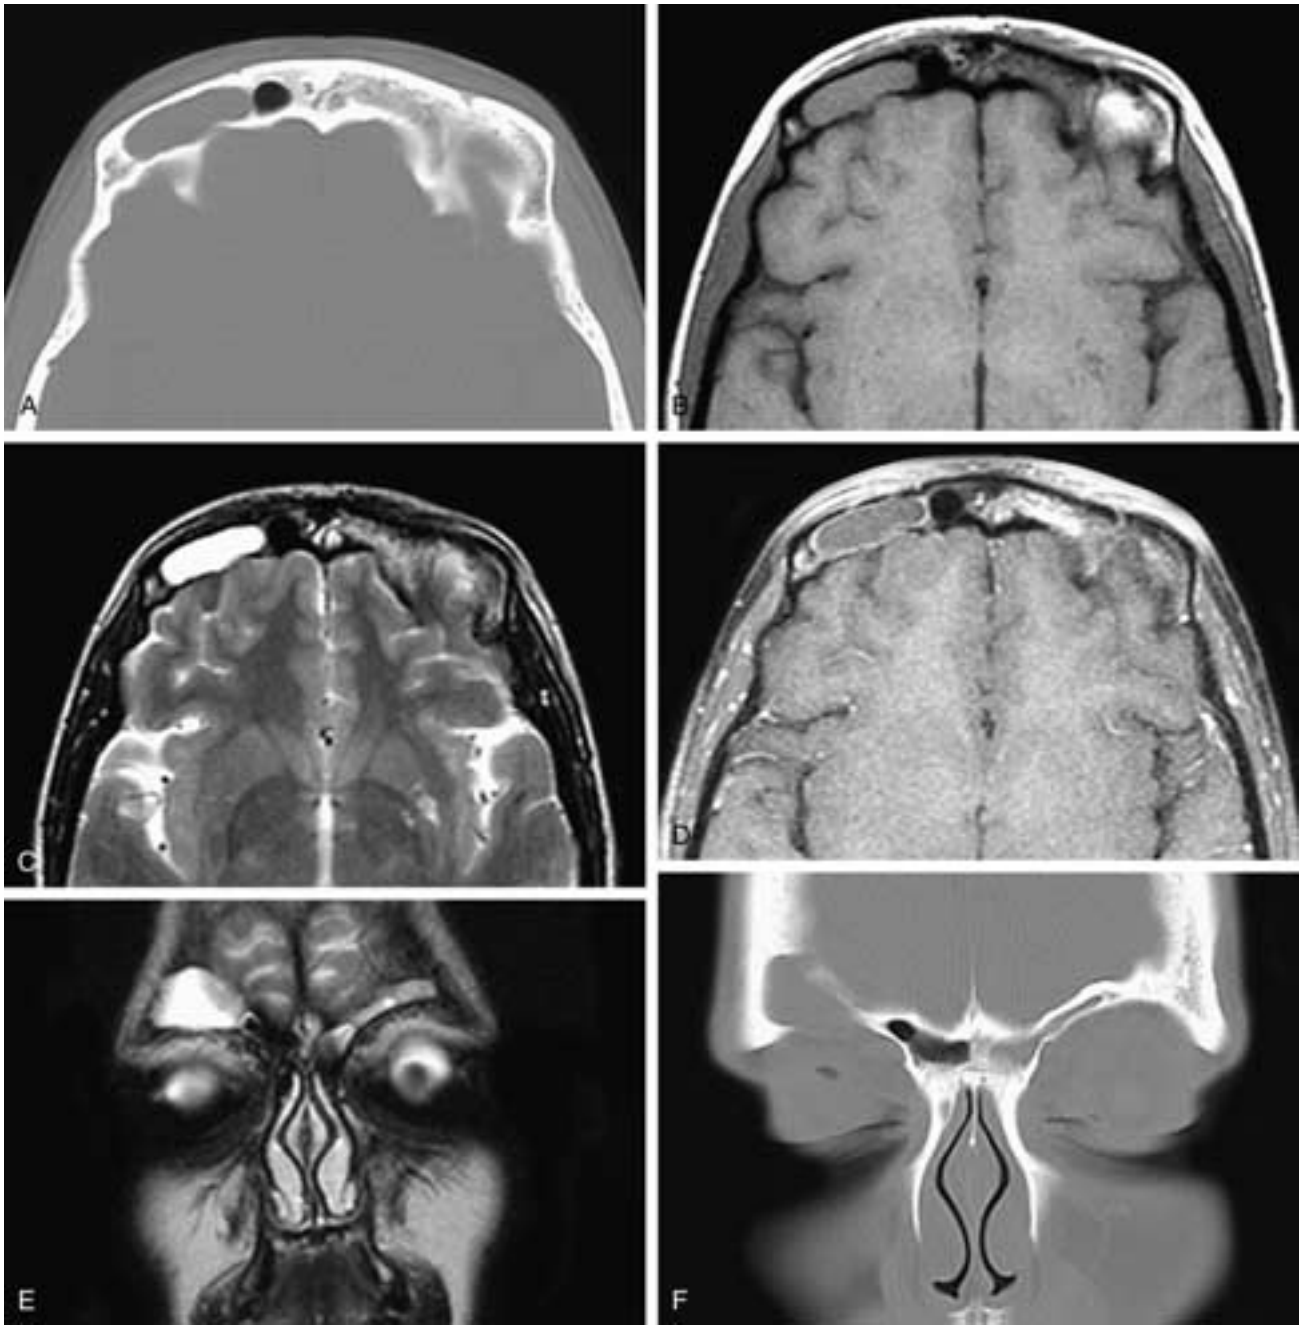

FIGURE 5-113 Axial CT scan (**A**) shows a smoothly marginated mass in the right frontal bone. The medial aspect of the mass abuts on the right side of the right frontal sinus. Axial T1-weighted (**B**) and T2-weighted (**C**) MR images show the mass to have an intermediate T1-weighted and high T2-weighted signal intensity. Axial T1-weighted, fat-suppressed, contrast-enhanced MR image (**D**) shows some enhancement around the margins of the mass. Coronal T2-weighted (**E**) MR image and coronal CT scan (**F**) show that the mass is adjacent to the right frontal sinus and has broken down into the roof of the right orbit. There is also some inflammatory disease in the left supraorbital sinus. This patient had a cholesteatoma of the right frontal bone.

distance Caldwell view (10.3%), if a line drawn from the base of the crista galli to a point of maximum distance along the perimeter of the sinus exceeds 74.4 mm (head unit) or 79.3 mm (posteroanterior skull film), the sinus is larger than 99% of normal frontal sinuses and may be referred to as a *hypersinus*. This term refers to an enlarged, aerated sinus that does not expand its normal bony contours (Figs. 5-114 and 5-115).

Pneumosinus dilatans refers to an aerated sinus that is abnormally expanded (either the entire sinus or a portion of the sinus). The sinus walls are intact and of normal thickness, but remodeled and outwardly displaced. Pneumosinus dilatans may result in frontal bossing, diplopia, or a nasal mass, depending on which portion of the sinus is expanded. Accordingly it is this extension of the sinus beyond the normal bony boundaries that differentiates pneumosinus dilatans from hypersinus. If the entire sinus is not involved, the remaining sinus dimensions are usually normal (Fig. 5-116).[147, 148]

Pneumocele refers to an aerated sinus with either focal or generalized sinus cavity enlargement and thinning of the bony sinus walls. It is the latter feature that differentiates pneumosinus dilatans from a pneumocele (Figs. 5-117 to 5-121). This distinction stems from the clinical literature, where the integrity, or lack of integrity, of the sinus wall was observed as a differentiating point. Although a ''valve'' theory has been suggested as an etiology for the delayed pressure equilibration that apparently occurs in pneumoceles, no such valve has been demonstrated physiologically.

At present there is no clear understanding of the factors that either influence the development of normal sinuses or signal the normal cessation of sinus growth. Consequently the etiology of excessive sinus aeration and growth that produces hypersinus, pneumosinus dilatans, and pneumocele is unclear.[146] The pneumocele's growth can be arrested by creating a surgical window (i.e., antrostomy, ethmoidectomy, sphenoid sinusotomy) to allow rapid pressure equilibration. The cosmetic deformity that may result from either a pneumosinus dilatans or a pneumocele can be dealt with surgically if necessary by collapsing the sinus.

In the sphenoid sinus, the planum sphenoidale may be bowed cranially by an overlying meningioma simulating pneumosinus dilatans on imaging.[149] However, a meningioma will bow primarily the sphenoid roof, sparing the other sinus walls. The intracranial component of the meningioma can then be confirmed on CT or MR imaging. The sphenoid bone is usually thickened and sclerotic adjacent to the neoplasm.

Enlarged, aerated frontal sinuses may also be seen in systemic conditions such as acromegaly, Dyke-Davidoff

SMALL OR ABSENT AERATED SINUSES

Small or absent but aerated sinuses are associated with a variety of abnormalities. A hypoplastic small sinus may be the result of developmental failure or encroachment from expanding sinus wall bone. Hypoplastic sinuses are associated with syndromes such as Binder's syndrome (maxillonasal dyplasia or maxillovertebral syndrome), Cockayne's syndrome, Down's syndrome, otopalatodigital syndrome (type 1), Prader-Willi syndrome, Schwarz Lélek syndrome, and Treacher Collins syndrome. Hypoplastic sinuses may also be the result of developmental bone abnormalities such as

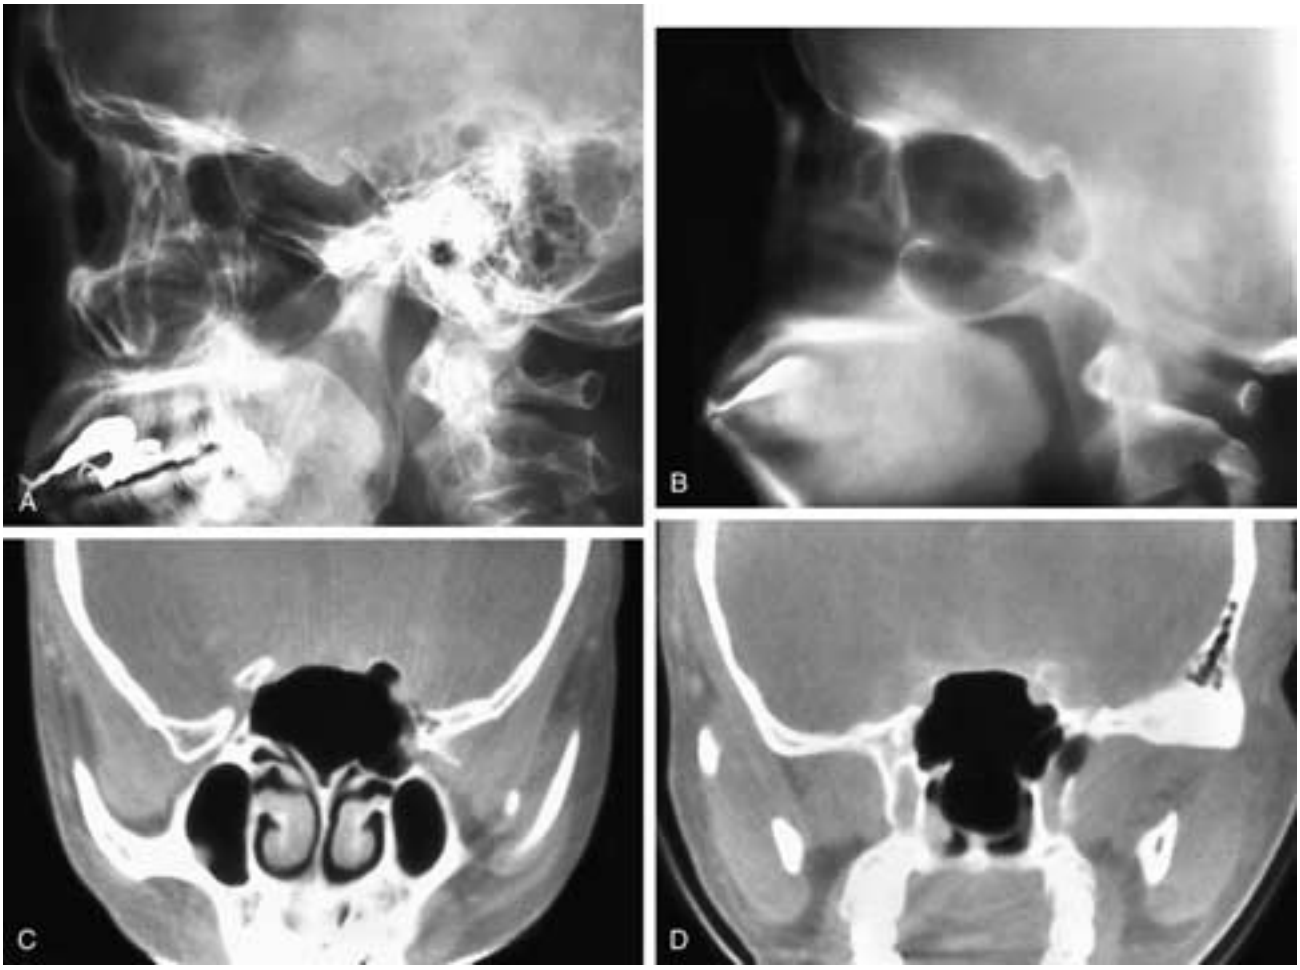
cleidocranial dysplasia, craniodiaphyseal dysplasia, craniometaphyseal dysplasia, fibrous dysplasia, frontometaphyseal dysplasia, frontonasal dysplasia, metaphyseal chondrodysplasia (Jansen type), osteodysplasty (Melnick needles), osteopathia striate with cranial sclerosis, osteopetrosis, pyknodysostosis, other conditions such as Paget's disease, and hematologic conditions that affect the marrow space such as sickle cell anemia and thalassemia. Hypoplastic sinuses may also be associated with endocrine diseases such as hypopituitarism and hypothyroidism.[150] Lastly, irradiation to a child's face can destroy the bony growth center and result in a hypoplastic bone. As a result of the small bone, the sinus cavity within the bone is small.

COMPLICATIONS OF INFLAMMATORY PARANASAL SINUS DISEASE AFFECTING ADJACENT AREAS

In the present antibiotic era, most acute paranasal sinus infections are successfully treated. It is only in a few cases



VIEW IMAGE

FIGURE 5-121 Lateral plane film **A** and multidirectional tomogram **B** show an expanded sphenoid sinus with thinned bony sinus walls. The sinus floor is displaced downward so that it rests atop the soft palate, the planum sphenoidale is elevated, and the posterior clivus is bowed backward. Coronal CT scans through the anterior **C** and the posterior **D** sphenoid sinus show the thinned bony walls and extension of the sinus into a pneumatized and expanded left anterior clinoid process. This patient had a pneumocele. When he traveled in an airplane, the sphenoid sinus expanded and compressed his left optic nerve, causing visual symptoms. He was cured by surgery.

that surgical intervention is required to help control an acute infection. However, a delay in initiating proper treatment, organisms resistant to the chosen antibiotics, or incomplete treatment regimens all can allow an initially localized infection to spread to adjacent regions.[151, 152]

About 3% of patients with paranasal sinusitis experience some related orbital or preseptal inflammatory disease. These various complications include retention edema of the eyelids, preseptal cellulitis, preseptal abscess, orbital cellulitis, subperiosteal orbital abscess, orbital abscess, and cavernous sinus thrombosis.[151, 153] Such orbital complications are discussed in Chapter 9. In addition, 15% to 20% of the cases of retrobulbar neuritis are secondary to posterior ethmoid and sphenoid sinusitis, and in some of these cases the neuritis can apparently occur without other manifestations of orbital inflammatory disease.[76, 154]

The ethmoid sinuses are clearly most often implicated as the source of infection for orbital complications. The thin lamina papyracea and the anterior and posterior valveless ethmoidal veins allow rapid access of infection into the orbit.[155] Sinusitis of the sphenoid, maxillary, and frontal sinuses are, in descending order, less likely to cause orbital infection.

Inflammatory pseudotumor (IMF), also referred to as *inflammatory myofibroblastic tumor*, is a fibro-inflammatory space-occupying lesion or, most likely, a number of entities with overlapping histologic features, the true nature of which is only beginning to be elucidated. The lung, liver, and gastrointestinal tract (omentum and mesentery) are the most common sites for IMF. Orbital inflammatory pseudotumors are a broad category of idiopathic, nonspecific, nonneoplastic, chronic inflammatory processes without identifiable local or systemic causes. On rare occasions, mucosal thickening in the nasal fossae and paranasal sinuses is seen in patients with concurrent orbital pseudotumor. These mucosal changes may be noninfectious and consistent with pseudotumor.[156] The association of the orbital and sinonasal diseases may suggest this diagnosis; however, more commonly, orbital pseudotumor is either an isolated finding or is associated with routine, unrelated sinonasal inflammatory disease.

Maxillary sinus pseudotumor can also occur without associated orbital complications. Unlike its orbital counterpart, which rarely involves the adjacent bone, antral pseudotumor usually presents with areas of bone erosion, sclerosis, and remodeling, often mimicking the imaging appearance of an aggressive fungal infection or an antral malignancy (Figs. 5-123 and 5-124).[157] The differential diagnosis of such orbital and sinonasal disease must also include Wegener's granulomatosis.

Occasionally sinusitis can lead to intracranial complications such as meningitis, epidural abscess, subdural abscess, cerebritis, and cerebral abscess (Fig. 5-10).[158] Only 3% of intracranial abscesses are the result of sinusitis, most commonly frontal sinusitis, followed in descending order by sinusitis in the sphenoid, ethmoid, and maxillary sinuses. The propensity for frontal sinusitis to spread intracranially is due to the rich emissary network (Beçhet's plexus) connecting the posterior sinus mucosa with the meninges.[151]

Both of these patients had antral pseudotumors.

VIEW IMAGE

Osteomyelitis can be a complication of chronic, smoldering bacterial or fungal sinusitis or sinusitis in patients with previous irradiation to the facial bones. The dominant clinical finding is persistent pain; the radiographic manifestations include focal rarefaction of bone, sequestrum formation, reactive thickening of the bone, bony sclerosis, and ultimately fragmentation of the bone.

Over the frontal sinus, a subgaleal abscess can form secondary to sinusitis. This occurs via osteothrombophlebitis and may or may not be associated with frank osteomyelitis. This subgaleal abscess is also called a Pott's puffy tumor.[159, 160]

Overall, intracranial and intraorbital complications are more likely seen with acute sinusitis, whereas osteomyelitis is more likely a complication of chronic sinusitis.

THE NEED FOR PREOPERATIVE IMAGING

Chapters 2 and 3 discussed numerous anatomic variations between and within individuals. Some of these are incidental findings. However, if the surgeon is unaware of these variations prior to surgery, operative complications may occur. In addition, if preoperative imaging is not performed, unknown pathology that may influence treatment decisions can be overlooked (Fig. 5-125). Thus it is strongly recommended that prior to any sinus surgery, an imaging study should be performed.

FOREIGN BODIES

A great variety of foreign bodies have been reported in the sinonasal cavities. Some are made of plastic materials (e.g., beads) or other nonradiopaque materials (e.g., gauze) that cannot be visualized on plain films, and others are radiodense (i.e., metallic) and can be localized easily on routine radiographic examinations (Fig. 5-126). If a foreign body is present for a sufficiently long time, it may act as a nidus and become encrusted with mineral salts. As such, these calcified masses are referred to as either rhinoliths or sinoliths, depending on whether they are located in the nasal fossa or a paranasal sinus, respectively (Figs. 5-127 to 5-129).[161, 162] If on CT a solitary calcification is seen within a sinus cavity, invariably it is the result of infection. Nearly 50% of the time that multiple discrete intrasinus calcifications are present, the cause is infection, often of a fungal etiology.[163] Tumors also account for about 50% of the cases of multiple sinonasal calcifications. The most likely lesions are olfactory neuroblastoms, inverted papilloma, or a chondroid tumor. Rarely, intrasinus ossification can occur, the implications being the same as those of calcifications.

ANOSMIA

The two most common causes of anosmia are of an idiopathic origin and secondary to sinonasal inflammatory

Copyright © 2003, Mosby, Inc. All rights reserved.

disease. Usually, imaging shows essentially normal sinuses or inflammatory mucosal thickening obliterating the nasal olfactory recess(es). Intracranial disease may also result in anosmia, for instance Kallman's syndrome, which consists of a primary eunuchoidism, secondary to hypogonatropic hypogonadism, and associated congenital anosmia, usually with absence of the olfactory bulbs and tracts. Coronal MR images best show the absence of these olfactory structures and allow differentiation of this syndrome from the other more common causes of anosmia (Fig. 5-130).[164–167]

SYNDROMES AND SINUSITIS

Sinusitis may be associated with numerous clinical syndromes, which are briefly reviewed in this section.

Kartagener's Syndrome

Kartagener's syndrome is an autosomal recessive inherited disease characterized by the clinical triad of bronchiectasis, sinusitis, and situs inversus. It is caused by an ultrastructural defect in the cilia that results in impaired mucociliary clearance. It is usually diagnosed during childhood, with only a small number of cases discovered in adults. Prompt, appropriate treatment of respiratory infections can minimize irreversible lung damage.[168]

Primary Ciliary Dyskinesia Syndrome

Primary ciliary dyskinesia, also known as immotile cilia syndrome and dyskinetic cilia syndrome, is the generic term for a heterogeneous group of inherited diseases with motility

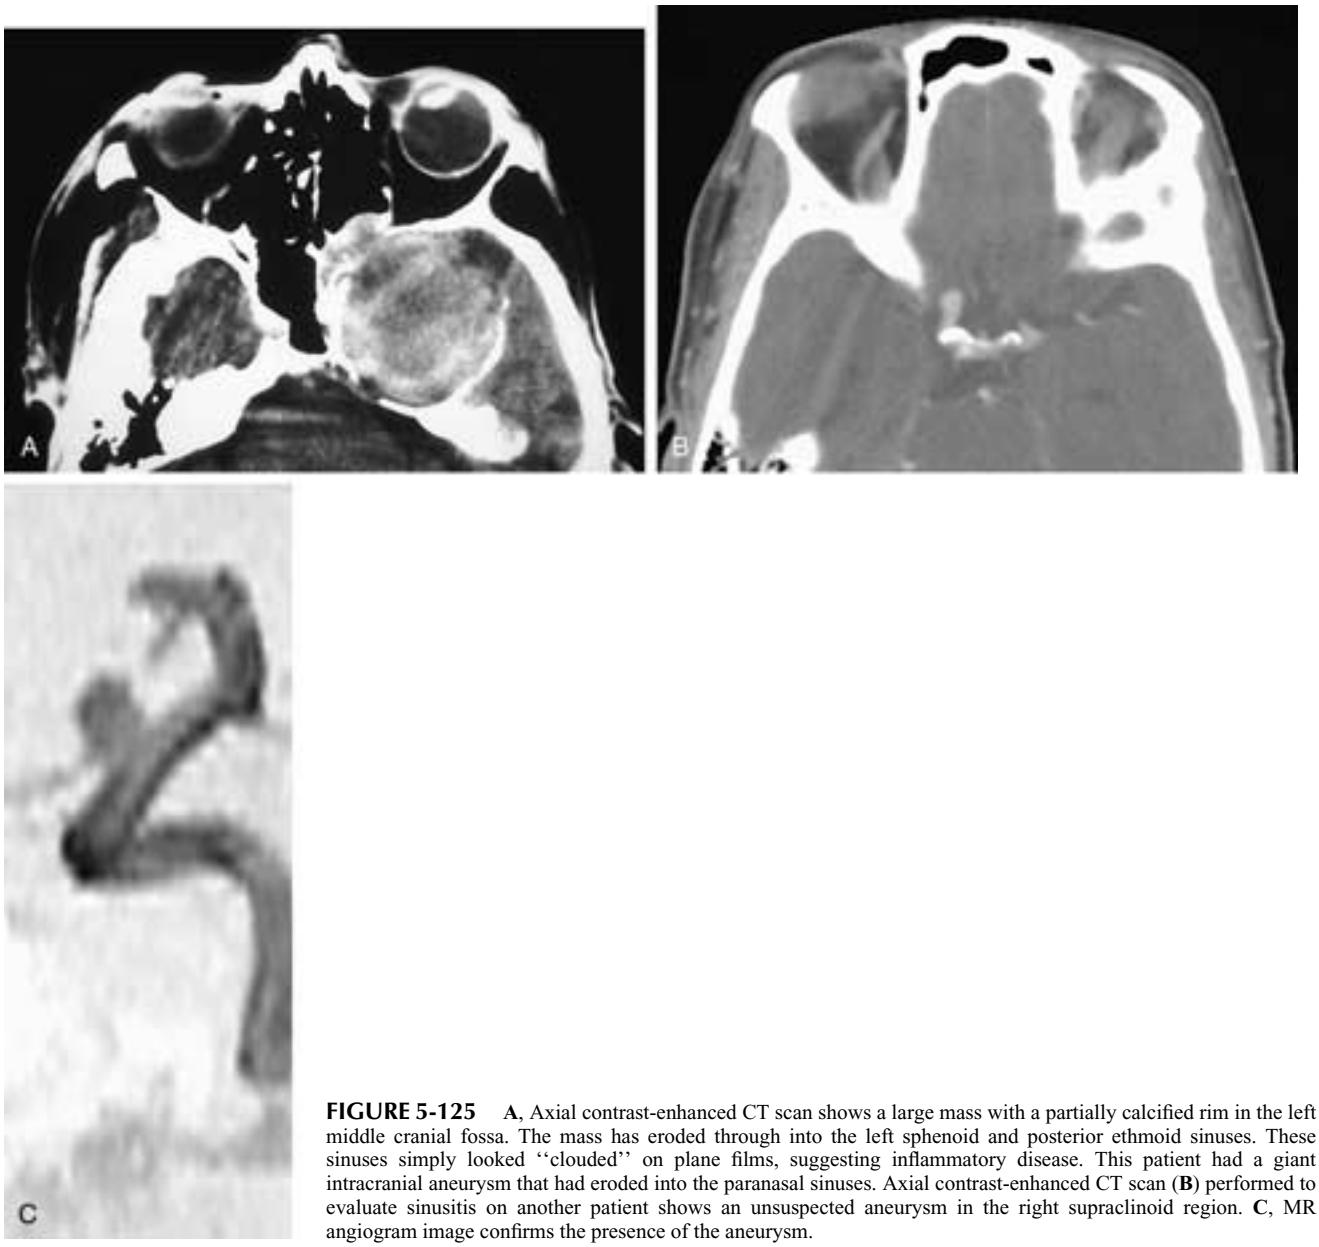

FIGURE 5-125 **A**, Axial contrast-enhanced CT scan shows a large mass with a partially calcified rim in the left middle cranial fossa. The mass has eroded through into the left sphenoid and posterior ethmoid sinuses. These sinuses simply looked ''clouded'' on plane films, suggesting inflammatory disease. This patient had a giant intracranial aneurysm that had eroded into the paranasal sinuses. Axial contrast-enhanced CT scan (**B**) performed to evaluate sinusitis on another patient shows an unsuspected aneurysm in the right supraclinoid region. **C**, MR angiogram image confirms the presence of the aneurysm.

disturbance resulting from defective ciliary ultrastructure. It is an autosomal recessive disorder with no sex predilection. Diagnostic criteria include chronic bronchitis, otitis, and childhood-onset sinusitis. Additionally, one or more of the following criteria must be present: Kartagener's syndrome, a dextrocardia situation, markedly reduced frequency in ciliary motility, or an essential ultrastructural deviation in more than 20% of the square cuts (e.g., reduced number of dynein arms). Vital microscopy and electron microscopy of the ciliated mucosa can distinguish primary and secondary ciliary dyskinesia and the rare case of primary ciliary dyskinesia without ultrastructural abnormalities. In special cases, establishing the cell tissue culture may allow for better ciliary evaluation and may be necessary for diagnosis.[169] Certain specific defects in the ciliary axoneme can be found, which are pathognomonic of the syndrome. The defects include missing dynein arms, abnormally short dynein arms, spokes with no central sheath, missing central microtubules, and displacement of one of the nine peripheral doublets. The most pronounced clinical manifestations are chronic paranasal sinusitis (52%) and chronic bronchiectasis (52%), followed by bronchopneumonia (26%), chronic bronchitis (21%), and nasal polyps (15%).[170, 171] Treatment with clarithromycin can be clinically useful in these patients.[172]

Young's Syndrome

Young's syndrome, also known as sinusitis infertility syndrome and Barry Perkins Young syndrome, is manifested by obstructive azoospermia and chronic sinopulmonary infection. Evaluation of nasal mucociliary transport reveals mucociliary stasis or decreased clearance. Ciliary ultrastructure is normal, but with decreased ciliary density, goblet cell hyperplasia, and low ciliary density. This is a chronic syndrome, which is less severe than syndromes with primary failure of mucociliary transport such as cystic fibrosis and primary ciliary dyskinesia. Young's syndrome should be considered in the differential diagnosis of patients suffering from chronic rhinosinusitis, particularly with cystic fibrosis and primary ciliary dyskinesia syndrome.[150, 173]

VIEW IMAGE

FIGURE 5-127 Coronal CT scan shows mucosal thickening in both ethmoid and maxillary sinuses, in the upper nasal fossae, and in both concha bullosa. In addition, there is a calcified rhinolith (*arrow*) in the right nasal fossa. This patient had sinusitis and a rhinolith.

VIEW IMAGE

Sertoli-Cell-Only Syndrome

The association of repeated sinus-bronchial-pulmonary infection and male infertility is well known in the literature in association with conditions such as cystic fibrosis, immotile cilia syndrome, and Young's syndrome. It is rarely seen otherwise. However, a patient with sinusitis, bronchiectasis, and sterility due to Sertoli-cell-only syndrome has been reported. Testicular biopsy showed absence of spermatogones and other germ cells, and nonspecific alterations were found in nasal cilia axonemes in the presence of DNA branches. A sweat test was negative. Recent studies have shown an increase in the prevalence of Sertoli-cell-only syndrome.[174]

Hyperimmunoglobulinemia E Syndrome

Hyperimmunoglobulinemia E syndrome, also known as hyper IgE syndrome, Job's syndrome, Buckley's syndrome, and HIE syndrome, is an autosomal recessive disease characterized by eczematoid dermatitis, recurrent suppurative skin infections, chronic purulent sinusitis, otitis media, pneumonia, impaired neutrophil chemotaxis, and high levels of serum IgE. There are also depressed specific cell-

FIGURE 5-128 **A**, Coronal CT scan shows inflammatory mucosal thickening in the right maxillary sinus and nasal fossa. A calcified rhinolith or sinolith is also present in the infundibulum (*arrow*). This patient had sinusitis and a sinolith/rhinolith. **B**, Coronal CT scan on another patient shows an intrasinus maxillary sinus tooth. This situation can occur when there is a highly situated, unerupted maxillary molar tooth.

mediated immune responses and a deficient antibody response.[150]

Churg-Strauss Syndrome

The Churg-Strauss syndrome is a rare multisystem disease classified among the various vasculitides. It occurs primarily in adults and is rare in children. The initial symptoms are usually bronchial asthma and allergic rhinitis and sinusitis, which may progress to pulmonary, cardiac, and renal manifestations. Typical symptoms include fever, weight loss, sinusitis, myalgia and arthralgia, testicular pain, pulmonary infiltrations, asthma, pericardial effusion, peripheral neuropathy, seizure, and eosinophilia. Biopsies reveal necrotizing arteritis with eosinophilia.[175] The Churg-Strauss syndrome should be considered in the differential diagnosis if bronchial asthma and resistant sinusitis occur coincidentally. It is often difficult to establish the diagnosis, and frequently the syndrome is diagnosed only after several

years. The therapy of choice is treatment with steroids, sometimes supplemented by cytotoxic drugs.[176] The long-term prognosis is good and does not differ from that of polyarteritis nodosa, although most patients need low doses of oral corticosteroids for persistent asthma even many years after clinical recovery from vasculitis.[177] However, the presence of severe gastrointestinal tract or myocardial involvement is significantly associated with a poor clinical outcome.

Nijmegen Paragraph Signbreakage Syndrome

Patients with nijmegen paragraph signbreakage syndrome (NBS) have microcephaly with decreased size of the frontal lobes and narrow frontal horns, agenesis of the posterior part of the corpus callosum with colpocephaly and temporal horn dilatation, callosal hypoplasia with abnormal CSF spaces and wide cerebral cortex, and pachygyria. The invariable sinusitis associated with NBS is a result of primary immunodeficiency. Like patients with ataxia telangiectasia and other breakage syndromes, those with NBS show an inherited susceptibility to malignancy and hypersensitivity to X and gamma radiation. CT is therefore contraindicated in these patients, and MR imaging should be the method of choice for diagnostic imaging.[178]

Croup

The etiology and clinical features of croup were studied in 132 children aged 3 months to 7 years. A diagnosis of laryngotracheobronchitis was made in 93.2%, and the pathogens identified included parainfluenza viruses, respiratory syncytial viruses, influenza A viruses, *Mycoplasma pneumoniae*, and adenoviruses. Bacterial tracheitis was present in 5.3% of cases, due to *S. viridans* and *Staph. aureus*. Fever of more than 3 days' duration was noted in 71% of children with bacterial tracheitis and in 28% of children with laryngotracheobronchitis. Among children with laryngotracheobronchitis, complications of pneumonia, acute otitis media, or sinusitis were more frequently observed when there was a fever for more than 3 days (40% versus 17% for those with fever of shorter duration). Thus children with fever of long duration and more severe manifestations of airway obstruction probably have bacterial croup syndrome or a complication thereof.[179]

Acquired Immune Deficiency Syndrome

Sinusitis is relatively rare among HIV-seropositive patients (3.3%) and may be clinically masked by other infections such as meningitis. Cure is difficult, relapses are frequent in spite of suitable treatment, and these are associated with a decline in immunocompetence.[180]

There is an amazing gamut of exotic agents that can cause sinusitis in seropositive patients, from algae to mushrooms. Bacterial sinusitis in patients with AIDS is caused by *P. aeruginosa* and *L. pneumophilia*, which are considered opportunistic bacterial pathogens that rarely cause sinusitis in normal hosts. Rare cases of *Microsporidium*-associated chronic sinusitis in HIV-seropositive patients have been reported, as have cases of *Septata intestinalis*–associated sinusitis. It appears that functional defects in local mucosal immunity may partially explain the acquisition of opportunistic mucosal infections in many HIV-seropositive patients.[181]

Aspirin Triad Syndrome

The aspirin triad syndrome is defined as aspirin sensitivity, asthma, and chronic sinusitis with polyposis. The sinusitis associated with this disease is often fulminant and difficult to treat. Surgical treatment may be necessary to control the sinusitis in the majority of these patients, and multiple procedures may be necessary for some patients. Controlling the sinusitis may alleviate the asthmatic symptoms and reduce the need for steroids. Long-term follow-up and aggressive medical management of chronic sinusitis will decrease the risk of orbital and other complications.[182, 183]

Copyright © 2003, Mosby, Inc. All rights reserved.

Silent Sinus Syndrome

Silent sinus syndrome was discussed earlier in this chapter. In response to chronic maxillary sinusitis, it is believed that a negative pressure develops within the obstructed sinus and, with time, the sinus walls collapse, allowing enophthalmus to occur.

Toxic Shock Syndrome

Toxic shock syndrome may occasionally be associated with sinusitis. A patient was described who presented with *S. pneumoniae* sinusitis, severe sepsis syndrome, and a desquamative rash.[184]

Cyclic Vomiting Syndrome

Although it remains a mysterious disorder since its description over a century ago, cyclic vomiting syndrome appears to be more prevalent than has been appreciated. Children are primarily affected, with vomiting that can range from an explosive, intermittent cyclic pattern to a low-grade, daily, chronic pattern. The etiologies causing a cyclic vomiting pattern include abdominal migraine, chronic sinusitis, intracranial neoplasm, anomalies of and mucosal injury to the gastrointestinal tract, urologic abnormalities, and metabolic and endocrine disorders. The cyclic pattern of vomiting is a symptom complex that can be induced by heterogeneous disorders that either cause or contribute to the vomiting. Once the cyclic vomiting pattern is identified, systematic diagnostic testing is warranted to look for these underlying disorders.[185, 186]

Yellow Nail Syndrome

Onset of the symptoms of yellow nail syndrome, also known as *yellow nails-bronchiectasis-lymphedema syndrome*, occurs in adults. It is characterized by thickened, smooth yellow- or green-colored nails with transverse ridging and excessive curvature, onycholysis, primary lymphedema due to lymphatic hypoplasia, chronic cough, pleural effusions, bronchiectasis, sinusitis, and a propensity to develop malignancies.[150, 187]

(P)FAPA Syndrome

The (P)FAPA syndrome (periodic fever, adenitis, pharyngitis, and aphthous stomatitis) was described in 1987. The etiology of this periodic syndrome remains unknown. In these children, this is an exclusionary diagnosis for a condition in which various treatments (antibiotics, antipyretics, nonsteroidal anti-inflammatory agents) have proved ineffective. The repetition of the periodic bouts of fever results in depressive disorders, absenteeism from school, and a drop in weight. In two of three patients there was chronic sinusitis, polyposis, and increased levels of immunoglobulin A. In all three patients, cimetidine was well tolerated and resulted in a disappearance of the periodic fever.[188]

Ataxia Telangiectasia Syndrome

Ataxia telangiectasia syndrome (Louis-Bar syndrome, Boder-Sedgwick syndrome, cephalo-oculocutaneous telangiectasis syndrome, sinopulmonary infectious syndrome) is either a familial (50%) or sporadically occurring autosomal recessive disease characterized by oculocutaneous telangiectasias, progressive cerebellar ataxia, and a defect in the cellular immunity of the immunoglobulin system. The last condition results in recurrent sinusitis and pulmonary infections. These patients have a predisposition to develop malignancies, endocrine disturbances, a high susceptibility to irradiation, and mental deficiency in one-third of cases. The onset of symptoms occurs in childhood.[150]

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome, also known as Wiskott-Aldrich-Huntley syndrome and eczema-thrombocytopenia syndrome, is as an X-linked recessive disorder that occurs in males. The onset of symptoms is in infancy or early childhood, and characteristically there is eczema, bloody diarrhea, recurrent infections (otitis, sinusitis, pneumonia), purpura, congenital thrombocytopenia, cellular and humoral immune deficiencies (without adenoidal development), anemia, and a predisposition to develop malignancies.[150]

Tumors and Tumor-like Conditions

Peter M. Som and Margaret S. Brandwein

GENERAL CONSIDERATIONS
BENIGN AND MALIGNANT EPITHELIAL TUMORS
- Papilloma
- Squamous Cell Carcinoma
- Adenocarcinoma (Intestinal-Type Adenocarcinoma)
- Salivary Tumors
  - Adenoid Cystic Carcinoma
  - Mucoepidermoid Carcinoma
  - Pleomorphic Adenoma
  - Epithelial-Myoepithelial Carcinoma

BENIGN AND MALIGNANT NEUROECTODERMAL, NEURONAL, NERVE SHEATH, AND CENTRAL NERVOUS SYSTEM TUMORS
- Paraganglioma
- Olfactory Neuroblastoma
- Sinonasal Neuroendocrine Carcinoma and Sinonasal Undifferentiated Carcinoma
- Malignant Melanoma
- Melanotic Neuroectodermal Tumor of Infancy
- Primitive Neuroectodermal Tumor and Ewing's Sarcoma
- Peripheral Nerve Sheath Tumors
  - Schwannoma
  - Neurofibroma
  - Traumatic Neuroma
  - Malignant Peripheral Nerve Sheath Tumor
  - Granular Cell Tumor
- Meningioma and Craniopharyngioma
- Chordoma
- Choristoma
  - Nasal Glioma
  - Ectopic Pituitary

LYMPHOPROLIFERATIVE AND HEMATOPOIETIC DISORDERS
- Lymphoma
- Granulocytic Sarcoma
- Multiple Myeloma
- Extramedullary Plasmacytoma
- Langerhans' Cell Granulomatosis
- Rosai-Dorfman Disease
- Thalassemia

BENIGN AND MALIGNANT PRIMARY SOFT-TISSUE TUMORS
- Vascular
  - Angiofibroma
  - Angiomatous Polyp
  - Hemangioma
  - Angiosarcoma
  - Hemangiopericytoma
  - Kaposi's Sarcoma
- Muscle
  - Leiomyoma and Leiomyosarcoma
  - Rhabdomyoma
  - Rhabdomyosarcoma
- Lipoblastic
  - Lipoma and Lipoma-Like Lesions
  - Liposarcoma
- Fibroblastic
  - Fibrosarcoma (Including Desmoid Tumor)
  - Malignant Fibrous Histiocytoma
  - Benign Fibrous Histiocytoma
  - Inflammatory Myofibroblastic Tumor
  - Solitary Fibrous Tumor
  - Fibromyxoma and Myxoma

BENIGN AND MALIGNANT OSSEOUS LESIONS AND TUMORS (INCLUDING FIBROOSSEOUS LESIONS)
- Benign Tumors
  - Osteoma and Exostosis
  - Osteochondroma
  - Chondroma
  - Osteoid Osteoma and Osteoblastoma

Copyright © 2003, Mosby, Inc. All rights reserved.

Ossifying Fibroma (Cemento-Ossifying Fibroma)
Tumor-Like Conditions and Giant Cell–Rich Lesions
Fibrous Dysplasia
Cemento-Ossifying Dysplasia
Cherubism
True Giant Cell Tumor
Giant Cell (Reparative) Granuloma
Aneurysmal Bone Cyst
Paget's Disease
Sarcomas
Osteogenic Sarcoma and Chondrosarcoma
Mesenchymal Chondrosarcoma
ODONTOGENIC LESIONS AND TUMORS
Jaw Cysts
Follicular Cyst
Periodontal Cyst
Odontogenic Keratocyst
Calcifying Odontogenic Cyst
Fissural Cyst
Developmental Cyst
Odontogenic Tumors
Ameloblastoma (Including Unicystic Ameloblastoma)
Cementoblastoma
Odontoma
Calcifying Epithelial Odontogenic Tumor
HAMARTOMAS, TERATOMAS, AND TERATOCARCINOMAS
METASTATIC DISEASE TO THE SINONASAL CAVITIES

GENERAL CONSIDERATIONS

The sinonasal tract plays host to an enormous variety of neoplasms derived from a multitude of tissue types. Sinonasal neoplasias can be broadly classified as either epithelial or mesenchymal. Epithelial neoplasia may arise from the Schneiderian lining mucosa (e.g., papillomas, squamous carcinomas, intestinal-type adenocarcinoma), minor salivary tissue (which includes the whole array of benign and malignant minor salivary tumors), neuroendocrine tissue (e.g., sinonasal neuroendocrine carcinoma), or olfactory mucosa (olfactory neuroblastoma). Each of the mesenchymal tissues of the sinonasal tract can give rise to benign and malignant neoplastic counterparts. Thus one can expect an array of tumors with benign, malignant, or unknown biologic potential, recapitulating their tissue of derivation (bone, cartilage, fibroblasts, smooth and skeletal muscle, vessels, etc.).

By comparison to the ubiquitous nature of sinonasal inflammatory disease, neoplasms affecting the paranasal sinuses and nasal cavities are rare. Carcinomas are by far the most common neoplasm, yet they comprise only 0.2% to 0.8% of all malignancies and about 3% of all malignant tumors that arise in the head and neck.[1] In the SEER (surveillance, epidemiology, and end results) data of the National Institutes of Health, which followed more than 50,000 upper aerodigestive tract malignancies from 1973 to 1987, only 3.6% of these tumors occurred in the sinonasal tract.[2]

Despite their statistically low incidence, sinonasal malignancies are a clinically significant group of neoplasms with an overall grave outlook. They usually present at an advanced tumor stage, and often surgeons are reluctant to be appropriately aggressive for fear of creating either an undesirable cosmetic deformity, prolonged morbidity, or gross dysfunction. Furthermore the complex, compact anatomy of the region often limits the extent of surgical resection and contributes to serious radiotherapeutic complications.[3, 4] Although surgery remains the primary treatment modality, combined chemotherapy and radiation therapy now play a significant role for these patients, especially for those who present with advanced disease.

Sinonasal tumors can remain clinically silent until they reach an advanced stage. In addition, coexisting infection can overshadow the clinical presentation, further delaying diagnosis. Patients with antral and ethmoidal cancers have an average delay of 6 months between the onset of symptoms and the establishment of a final diagnosis.[3] Pain secondary to malignancy usually signifies an advanced tumor stage and possible perineural tumor invasion, especially with adenoid cystic carcinoma. Tooth or gum pain may indicate an antral tumor, whereas a headache may signify skull base invasion and intracranial extension. Inexplicably, pain is not often associated with the bone destruction that accompanies these tumors. Common complaints of patients with sinonasal tumors include diplopia, decreasing vision, proptosis, nasal stuffiness, anosmia, nasal-quality voice, epistaxis, and a facial mass. Maxillary sinus tumors cause trismus, epiphora, orbital pain, proptosis, or trigeminal or sphenopalatine ganglion–related deficits secondary to dorsal tumor spread. Ethmoid tumors usually cause nasal stuffiness, orbital complaints, and headache from intracranial tumor spread. Frontal sinus tumors may deform the face, spread intracranially, or extend into the orbits, while sphenoid sinus tumors can extend into the nasopharynx, intracranially (especially to the cavernous sinuses), and into the orbit.

With improved imaging technology, superior tumor mapping and staging are now available, and this accurate information permits more realistic treatment planning with regard to cure versus palliation.[5] Surgical techniques have also improved, and better tumor extirpation can be achieved with less morbidity and facial deformity. In addition, enhanced tumor mapping equates with more accurate

VIEW IMAGE

FIGURE 6-1 Coronal (**A**) and axial (**B**) T2-weighted MR images show a polypoid, nonhomogeneous right nasal fossa mass that has intermediate signal intensity. The right maxillary sinus, the right lateral ethmoid sinuses, and the lower nasal fossa have high signal intensity material that represents obstructed secretions. The tumor does not extend directly to the orbital margin. Such a high degree of tumor mapping was not possible on CT, where the secretions and tumor had similar attenuations. This patient had an inverted papilloma and obstructed secretions.

placement of radiation fields. To provide the tumor mapping necessary for decisions regarding resectability and curability, the radiologist must be aware of the critical areas of tumor extension that will alter a surgical or irradiation treatment plan. These areas include tumor extension into the floor of the anterior and middle cranial fossae, the pterygopalatine fossae, the orbits, and the palate.[6] The proximity of the paranasal sinuses and their structural communication via the nasal fossae allow tumor spread between sinuses. Thus the radiologist must describe in detail the sinus and the precise areas within each sinus that are apparently affected by neoplasm. Although primarily a communication tool with clinicians, gray scale and color 3D reconstructions allow the tumor to be visualized within the framework of the facial bones and skull base. Newer treatment-planning computers are now able to utilize the raw data of these images to help prepare treatment plans.[7]

Nodal metastasis from sinonasal carcinomas is one of the gravest prognostic signs. The retropharyngeal nodes are the primary lymph nodes draining the paranasal sinuses and nasal vault. However, these nodes or their lymphatic channels are frequently obliterated by repeated childhood infections. Accordingly, for adults, sinonasal malignancies often metastasize to the secondary nodes in levels I and II (see Chapter 36). Such nodal metastases occur in approximately 15% of patients and are associated with tumor extension to the skin, alveolar buccal sulcus, or pterygoid musculature, often as demonstrated on CT and MR studies.[4] Thus the radiologist should be thorough and precise in reporting tumor extension in these sites. The presence of cervical nodal disease is predictive of distant metastases, which have been found in 34% of autopsied patients.[6]

One of the major imaging problems of precise tumor mapping is distinguishing tumor from adjacent inflammatory disease. Basing this distinction on routine CT attenuation values is fraught with inaccuracies. Contrast-enhanced CT can improve the results; however, MR imaging is superior in making this distinction. Inflammatory secretions and tissues have high water content and thus have high T2-weighted signal intensities (see Chapter 5). By comparison, virtually all sinonasal tumors are highly cellular, with relatively little intracellular and intercellular water, and the majority of these tumors have an intermediate signal intensity on T2-weighted images (Figs. 6-1 and 6-2).[8, 9] Thus, the mainstay of the MR imaging distinction between tumor and adjacent inflammatory tissues is the T2-weighted MR sequence. It is rare for sinonasal tumors to have inherently high T2-weighted signal intensities, which may be seen with benign or low-grade minor salivary gland tumors, schwannomas, rare hemangiomatous lesions, and polypoid tumors such as inverted papillomas. Therefore these tumors may not be as amenable to accurate T2-weighted tumor mapping.

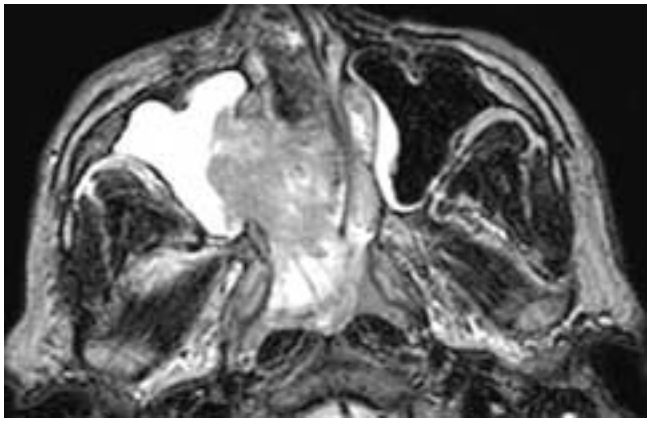

FIGURE 6-2 Axial T2-weighted MR image shows a large right-sided nasal fossa mass that has destroyed most of the medial wall of the right maxillary sinus and extends back into the nasopharynx. The mass has areas of high signal intensity that represent sites of necrosis. The right maxillary sinus is obstructed, and inflammatory mucosal thickening is seen in the left antrum. This patient had a squamous cell carcinoma and obstructed secretions.

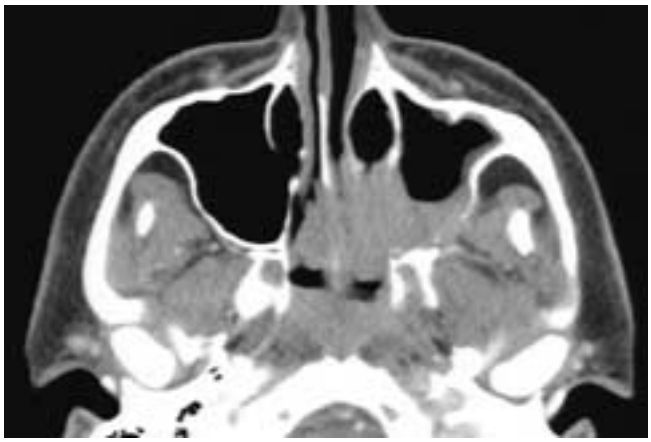
FIGURE 6-3 Waters view shows that the lateral wall of the left maxillary sinus is totally destroyed (*arrow*). The right lateral antral wall is intact. This is an example of aggressive bone destruction. This patient had a squamous cell carcinoma of the left antrum.



VIEW IMAGE

FIGURE 6-4 Axial CT scan shows a destructive mass in the left posterior nasal fossa that has destroyed portions of the medial and posterior left maxillary sinus walls. There is also some destruction of the left pterygoid process, and tumor extends into the left retromaxillary fat. This patient had a squamous cell carcinoma.

Small tumors may often elude clinical and radiologic detection. Unfortunately, it is at this early stage that tumors may be most curable.[4] Small sinonasal tumors often have MR characteristics indistinguishable from those of adjacent inflammation. In addition, radiologists are reluctant to diagnose a tumor in the absence of adjacent bone involvement. Thus, on imaging, many small tumors are often misdiagnosed as inflammatory polypoid disease. Bony changes are seen in larger tumors and allow for a more definitive imaging diagnosis of neoplasm. The pattern of bone involvement (either aggressive bone destruction or bone remodeling) can aid in generating a radiographic differential diagnosis.[10–12]

Squamous cell carcinoma is associated with aggressive bone erosion, usually with only small bony fragments remaining (Figs. 6-3 to 6-6). Metastatic carcinomas, as well as some sarcomas and lymphomas, can also cause aggressive bone destruction, but they are less often encountered. By comparison, most sinonasal mucoceles, polyps, inverted papillomas, and rarer lesions such as minor salivary gland tumors, schwannomas, extramedullary plasmacytomas, most lymphomas, olfactory neuroblastomas, most sarcomas, and hemangiopericytomas tend to primarily remodel rather than aggressively destroy bone (Fig. 6-7).

For most tumors, one of these patterns of bone involvement appears to be dominant. Although the bony pattern is not sufficiently specific to predict histology, the radiologist can still use the type of bone involvement to occasionally question some histologic diagnoses. Thus, if a patient has a unilateral polypoid nasal mass and a microscopic diagnosis of a ''large cell lymphoma,'' but the radiographic pattern of bone destruction is predominantly aggressive, the radiologist might question this diagnosis and recommend ancillary diagnostic tests such as immunohistochemistry. This might lead to a diagnosis such as ''sinonasal undifferentiated carcinoma'' (SNUC), which is in the pathologic differential diagnosis of large cell lymphoma. In fact, immunohistochemistry is routinely performed for all sinonasal ''round cell'' tumors to distinguish between SNUC, sinonasal neuroendocrine tumor (SNEC), olfactory neuroblastoma, malignant lymphoma, embryonal rhabdo-

FIGURE 6-6 Coronal T1-weighted MR image shows a large intermediate signal intensity mass that fills the right ethmoid complex and nasal fossa. The tumor extends into the right orbit, and there is erosion of part of the roof and medial floor of the right orbit, the fovea ethmoidalis, and the right cribriform plate, as evidenced by the loss of the bone signal void in these areas. The right maxillary sinus is obstructed by the tumor. This patient had a squamous cell carcinoma.

myosarcoma, extramedullary plasmacytoma, olfactory neuroblastoma, and amelanotic melanoma. Immunohistochemistry may be performed on unstained slides from the original biopsy (Table 6-1).

Tumor biology and prognosis are multifaceted issues. Host immune surveillance may limit tumor growth for a variable period of time, sometimes for many years. Successive activation of tumoral oncogenes or additional loss of tumor suppressor genes correlates with tumor progression or the acquisition of aggressive features (see Chapter 44), but the lethal propensity of certain tumors is, unfortunately, poorly understood. In addition to tumor biology, the critical anatomic location of the neoplasm has prognostic significance. Thus a lesion confined to the antrum generally has a better prognosis than one located in the pterygopalatine fossa or central skull base. However, certain tumors are highly aggressive regardless of location and despite a noninfiltrating imaging appearance. For example, a nasal fossa melanoma usually has a benign polypoid imaging appearance, yet the 5-year survival prognosis is abysmal (Fig. 6-8). Thus, the invasive, or lack of invasive, margins of a tumor cannot always be used to predict biologic aggressiveness. Clearly, the pathologic diagnosis is more important in predicting prognosis than the imaging appearance of a tumor. Yet, the radiographic tumor mapping may also predict survival if critical anatomic areas are involved that are not readily amenable to treatment.

Sclerotic bone is usually not seen with neoplastic processes and is more commonly seen with bacterial inflammatory disease or more aggressive infection (e.g., fungal disease) or granulomatous disease. Frank sinonasal osteomyelitis usually appears as foci of bone rarefaction and sclerosis, often with sequestra. Radiation osteitis also can produce a similar bone reaction. Tumor invasion rarely causes osteoblastic bony sclerosis, but it can occur with

FIGURE 6-8 Coronal T1-weighted MR image shows a low signal intensity mass in the right ethmoid complex and nasal fossa. The tumor has broken into the right orbit, but the tumor interface with the orbital fat is smooth and not infiltrative. The right maxillary sinus is chronically obstructed with intermediate signal intensity secretions. This patient had a melanoma.

anaplastic carcinoma, nasopharyngeal carcinoma, and osteosarcoma. Fibrous dysplasia and ossifying fibroma both result in characteristic dense, expanded bone. The sclerotic facial bone changes of Paget's disease may be indistinguishable from those of osteoblastic metastatic prostate cancer, but the presence of associated pagetoid calvarial disease allows differentiation. Osteoblastic metastases from breast carcinoma can occur; however, such lesions are usually a mixed blastic and lytic process. Dense osteoblastic bone may also be found as a reaction to meningiomas.

Tumoral calcifications in the sinonasal cavities are uncommon. Discrete solitary or multiple calcifications within a mass usually signify a chronic inflammatory process, either bacterial or fungal. Such calcifications have also been reported with osteoblastomas, osteochondromas, chondromas, chondrosarcomas, and olfactory neuroblastomas. ''Calcifications'' can be seen in inverted papillomas; however, these radiodensities are actually foci of residual bone. Diffuse calcifications within a lesion with invasive margins auger a sarcoma rather than a carcinoma, usually either a chondrosarcoma, an osteosarcoma, or an undifferentiated sarcoma.

Copyright © 2003, Mosby, Inc. All rights reserved.

Despite the long list of diagnostic possibilities, a unilateral polypoid nasal mass with ''calcifications'' is most likely to be either an olfactory neuroblastoma or an inverted papilloma. A nasal septal mass with calcifications is most likely to be either a chondroid tumor or the result of fungal disease.

As mentioned, although the radiologist is constantly tempted to offer pathologic diagnoses, there are only rare instances in which the CT and MR imaging is specifically pathognomonic. Therefore, the primary radiographic contribution is accurate tumor mapping, with awareness of the critical anatomic sites that will influence treatment planning. Final treatment planning must await pathologic diagnosis.

BENIGN AND MALIGNANT EPITHELIAL TUMORS

Papilloma

The term *Schneiderian mucosa* refers to the ectodermally derived lining of the nasal cavity and paranasal sinuses, composed generally of stratified ciliated columnar cells, loose abundant lamina propria, and minor salivary glands and on their ducts. This unique mucosa may give rise to three distinct histomorphologic papillomas: fungiform, inverted, and oncocytic, collectively called Schneiderian papillomas.[1, 13] Schneiderian papillomas are uncommon, representing only 0.4% to 4.7% of all sinonasal tumors, which are 25 to 50 times less common than the pedestrian polyp.[13] These papillomas are not the result of allergy, chronic infection, smoking, or other noxious environmental agents, as they are almost invariably unilateral. It has been suggested that their rarity in children mitigates against a viral etiology.[14–16] However, many sensitive and specific viral studies confirm the association of fungiform and inverted papillomas with human papilloma virus.[17, 18]

Fungiform papillomas (septal, squamous, or exophytic) comprise 50% of Schneiderian papillomas. They usually occur in males between the ages of 20 to 50 years, and 95% arise on the nasal septum. They are solitary (75%) and unilateral (96%), have a warty or verrucous appearance, and are quite unlikely to undergo malignant transformation.[13, 14, 19] Histologically, fungiform papillomas have stratified keratinized squamous mucosa on fibrovascular stalks.

Inverted papillomas (endophytic papillomas) comprise 47% of Schneiderian papillomas and most commonly occur in males between the ages of 40 to 70 years. Characteristically, they arise from the lateral nasal wall near the middle turbinate and extend into the sinuses. This secondary extension involves the maxillary and ethmoidal sinuses, but extension into the sphenoid and frontal sinuses has been documented.[13, 14, 20] Rarely, an isolated inverted papilloma may arise within a sinus without any nasal involvement. Inverted papillomas rarely arise from the nasal septal wall, and fewer than 4% occur bilaterally.[13, 14] The most common presenting symptoms are nasal obstruction, epistaxis, and anosmia. Secondary sinusitis and tumor extension into the sinuses and orbits can cause pain, purulent nasal discharge, proptosis, diplopia, and a nasal vocal quality.

Macroscopically, inverted papillomas appear as hard white polyps with a wrinkled, prune-like surface. Microscopically, hyperplastic squamous epithelium can be seen replacing seromucinous ducts and glands, resulting in an endophytic growth pattern (Fig. 6-9). The surrounding mucosa usually reveals squamous metaplasia and hyperplasia, considered incipient changes. For this reason, mere polypectomy results in high recurrence rates that vary from 27% to 73%.[13] Lateral rhinotomy with en bloc resection of the lateral nasal wall and mucosa is the preferred procedure for all but the smallest localized lesions. This more extensive surgical approach has decreased recurrence rates to 0% to 14%, with most relapses occurring within 2 years.[13, 14] However, there has been a controversial trend over the last decade of more conservative endoscopic management, which is indicated only for the treatment of more limited lesions with planned surveillance. Thus, the radiologist may assist the surgeon in choosing the optimal surgical approach by not only mapping the lesion but noting its size.[21, 22]

Carcinoma-ex-inverted papilloma has been reported in 3% to 24% (average, 13%) of cases. Carcinoma may be concurrent with, or develop subsequent to, inverted papilloma. Most reported malignancies are squamous cell carcinomas, but verrucous carcinoma, mucoepidermoid carcinoma, spindle cell carcinoma, clear cell carcinoma, and adenocarcinomas may also occur.[13]

Oncocytic Schneiderian papillomas (cylindric cell papillomas) represent only 3% of the Schneiderian papillomas. They are similar to inverted papillomas in their affinity for the lateral nasal wall, age of onset, and predominance in males. On gross examination, they are beefy red and soft, mimicking malignancy. Microscopically, there are stratified, tall (cylindrical) oncocytic cells with numerous small intraepithelial cysts filled with mucin and neutrophils (Fig. 6-10). The cysts occasionally cause confusion with rhinosporidiosis, but slightly more than superficial perusal at high power can end this confusion.[13]

The imaging findings for all of these papillomas can vary from a small nasal polypoid mass to an expansile nasal mass that has remodeled the nasal vault and extended into the sinuses, causing secondary obstructive sinusitis[23] (Figs. 6-11 to 6-13). The MR and CT findings are nonspecific.[24, 25]

VIEW IMAGE

FIGURE 6-10 Oncocytic Schneiderian papilloma (cylindrical papilloma). This unusual form of Schneiderian papilloma is composed of tall oncocytes with a microglandular pattern. It can resemble, and may contain areas of, inverted papilloma.

Although apparent calcifications have been reported within the inverted papillomas, these radiodensities are in reality residual bone fragments.[21, 26] Nonetheless, the imaging differential diagnosis of a unilateral polypoid mass with apparent calcifications must include inverted papilloma (Fig. 6-14). The nasal septum usually remains intact, but it may be bowed to the opposite side by the mass. In patients with prior surgery including a medial antrectomy for an inverted papilloma, any polypoid mass that bridges the antral-nasal border on imaging must be considered a recurrence. A unilateral mass localized to the lateral nasal wall and the middle meatus region is predictive of inverted papilloma. A lobulated surface pattern, also typical, was noted in 19 of the 29 CT scans of cases.[27] Although a septal-based solitary polypoid mass could be any of these papillomas, the location most strongly suggests a fungiform papilloma. When an area of aggressive bone destruction is seen along the margin of an inverted papilloma, the radiologist must raise the possibility of an associated carcinoma.

Squamous Cell Carcinoma

Overall, cancer of the nasal cavity and paranasal sinuses is uncommon. In the United States, the incidence is reported to be 0.75 per 100,000 people.[28] From 25% to 58% of the sinonasal carcinomas arise in the antrum, 25% to 35% arise in the nasal cavity, 10% arise in the ethmoid complex, and only 1% arise in the sphenoid and frontal sinuses.[1, 13] Secondary extension to the maxillary sinus is common, occurring in 80% of patients with sinonasal carcinoma. A number of occupations have been epidemiologically linked to sinonasal malignancies. Workers exposed to nickel have a 40–250 times greater chance of developing squamous cell cancer.[29] Workers involved in the production of wood furniture, chromium, mustard gas, isopropyl alcohol, and radium are also at risk for developing carcinomas of the nasal cavity and paranasal sinuses. The latency period from onset of occupational exposure to tumor discovery may be up to three decades. Some 15% to 20% of the patients have a history of chronic sinusitis and polyposis; however, a causal relationship is doubtful.[13] Coexistent inverted and cylindric cell papillomas, previous irradiation, and immunosuppression (i.e., lack of immune surveillance) may increase the risk of developing sinonasal carcinoma.[13, 30] Metachronous or synchronous tumors are seen in 15% of patients with sinonasal carcinomas; 40% of the secondary tumors occur in the head and neck, and 60% occur below the clavicles in the lungs, gastrointestinal tract, and breasts.[13]

Histologically, squamous cell carcinoma (SCC) can be recognized as infiltrating broad bands, nested islands, or small clusters of malignant cells, which have a variable amount of eosinophilic cytoplasm. Keratin formation within cells, and between groups of cells (keratin pearls) belies the tumor's mucosal origins. Intercellular bridges may also be seen, appearing as fine hair-like connections between malignant cells (Fig. 6-15). Poorly differentiated or undifferentiated SCC produce little or no keratin by light microscopy. These cells can appear as oval malignant cells with little cytoplasm and large nucleoli, mimicking large cell lymphoma. They may be confirmed as

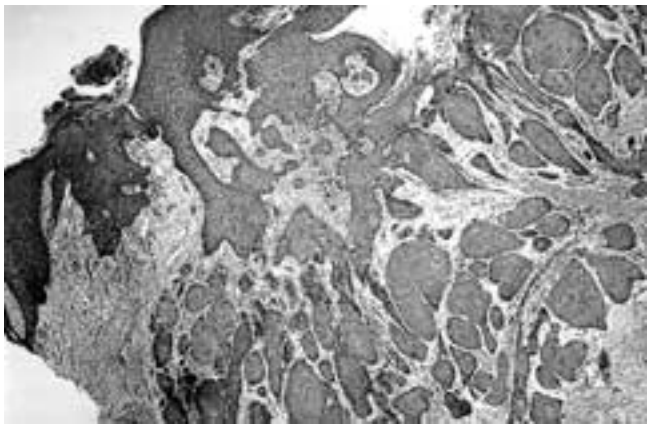
SCC by immunohistochemistry, which reveals keratin expression.

Carcinomas of the nasal cavity tend to occur in males between 55 and 65 years of age. Most are low-grade tumors arising on the nasal septum near the mucocutaneous junction. The middle turbinate is also a common site. Patient prognosis relates to tumor stage rather than exact site within the nasal cavity.[30, 31] The treatment may be surgery, irradiation, or both. Local recurrences are found in 20% to 50% of the cases, and about 80% of these develop within the first year. Only 15% develop nodal metastases and only 10% have distant metastases. The overall 5-year survival rate is 62%.

Carcinoma of the maxillary sinus has been the most extensively studied of the sinonasal malignancies. The specific site of origin of antral carcinomas is thought to have prognostic significance and is important in planning therapy and in comparing the treatment results of various medical centers. Historically, the antrum was divided into an infrastructure and a suprastructure; however, this classification was soon modified into an infrastructure, a mesostructure, and a suprastructure, with the lines of division being



VIEW IMAGE

VIEW IMAGE

FIGURE 6-16 Diagram of a coronal view of the sinonasal cavities. The lines divide the maxillary sinuses into three zones: suprastructure, mesostructure, and infrastructure. Tumors limited to and below the mesostructure usually can be resected by a partial or total maxillectomy without an orbital exenteration. Tumors involving the suprastructure usually need an orbital exenteration to reduce the chance of tumor recurrence.

drawn on a coronal view of the sinuses through the antral floor and the antral roof (Fig. 6-16).[32] Using this system, tumors limited to the mesostructure and infrastructure require a partial or total maxillectomy, whereas tumors that involve the suprastructure require a total maxillectomy and possible orbital exenteration. Ohngren divided the antrum into posterosuperior and anteroinferior segments by drawing a line on a lateral view of the face from the medial canthus to the angle of the mandible (Fig. 6-17). He suggested that tumors limited to the anteroinferior segment had a better prognosis.[32] It was not until the early 1960s that the TNM

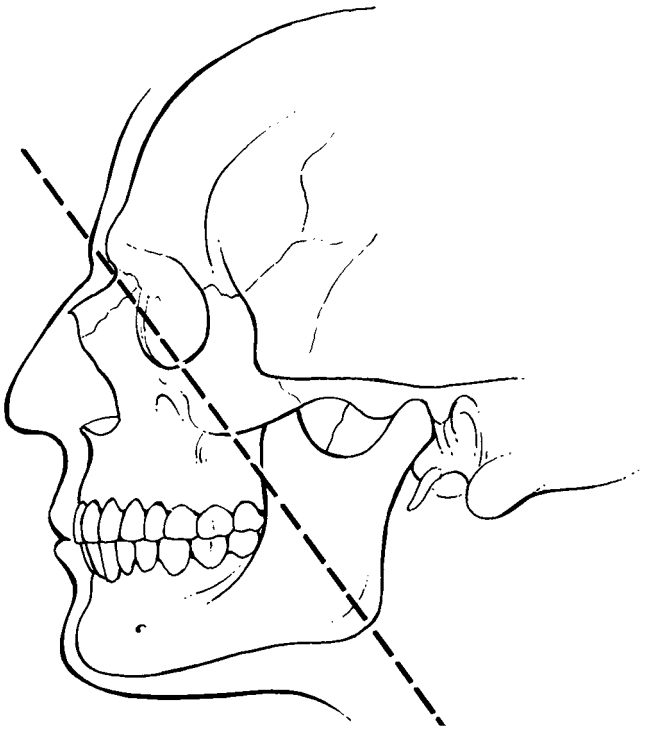

FIGURE 6-17 Diagram of the lateral view of a skull with Ohngren's line drawn. Tumors anterior to this line tend to have a better prognosis.

system was first applied to antral cancers, and in 1976 the American Joint Committee on Cancer (AJCC) developed a TNM system based on Ohngren's line.[32] Harrison has criticized this TNM classification because it does not correspond to the clinical experience with these tumors.[33] He suggested that T-1 tumors should be defined as those neoplasms that are limited to the antral mucosa, without bone erosion and without regard to Ohngren's line, because clinically it is often impossible to determine where this line occurs. A T-2 tumor has bone erosion but no extension beyond the bone, and a T-3 tumor has extension to the orbit, ethmoid complex, or facial skin. Finally, a T-4 tumor extends to the nasopharynx, sphenoidal sinus, cribriform plate, or pterygopalatine fossa. In 1997, the AJCC modified its staging definitions as follows: TX = the primary tumor cannot be assessed; T0 = no evidence of disease; Tis = carcinoma in situ; T1 = tumor limited to the antral mucosa, with no erosion or destruction of bone; T2 = tumor causing bone erosion or destruction, except for the posterior antral wall, including extension into the hard palate and/or the middle nasal meatus; T3 = tumor invasion of any of the following: bone of the posterior wall of the maxillary sinus, subcutaneous tissues, skin of the cheek, floor or medial wall of the orbit, infratemporal fossa, pterygoid plates, or ethmoid sinuses; T4 = tumor invasion of orbital contents beyond the floor or medial wall including any of the following: the orbital apex, cribriform plate, base of the skull, nasopharynx, sphenoid, or frontal sinuses.[34]

Antral carcinomas are almost twice as common in men as in women, and nearly 95% occur in patients over age 40 years.[13, 35] The radioactive contrast medium Thorotrast is clearly established as an etiologic factor in antral carcinoma.

When the tumors are small, they often are misdiagnosed as chronic sinusitis, nasal polyposis, lacrimal duct obstruction, tic douloureux, or cranial arteritis. At diagnosis, 40% and 60% of patients have facial asymmetry, a tumor bulge in the oral cavity, and tumor extension in the nasal cavity. At least one of these findings is present in almost 90% of cases.[36] Surgery plus adjuvant radiotherapy is the treatment of choice. Despite controversy in the literature, neoadjuvant radiation therapy provides no survival advantage compared to postoperative radiation therapy; the latter is associated with fewer complications.[13] Orbital exenteration is performed only if orbital periosteum is involved with tumor, as documented during surgery, either by gross examination or frozen section evaluation. Curative surgery generally is not attempted if there is central skull base destruction, tumor in the pterygopalatine fossa, tumor extension into the nasopharynx, regional or generalized metastases, advanced patient age, poor general patient health, or patient refusal to accept treatment.[13, 37] The 5-year survival rate varies from 20% to almost 40%, with mean figures ranging from 25% to 30%.[38] The main cause of failure is local recurrence, and 75% of these occur within 5 months of initial treatment.

Although more than 100 cases of primary frontal sinus carcinoma have been reported, it is still a rare entity. The presenting symptoms are similar to those of acute frontal sinusitis; patients have pain and swelling over the frontal sinus. However, in patients with frontal sinus carcinoma the frontal bone erodes rapidly, and few patients survive for more than 2 years.[4, 39]

Primary sphenoid sinus carcinoma is also rare. It is often difficult to distinguish primary sphenoid carcinoma from secondary extension from a posterior ethmoid or nasal fossa carcinoma. As with frontal sinus carcinomas, few of these patients survive longer than 1 or 2 years. Intracranial extension of squamous carcinoma is relatively common; however, an associated subarachnoid hemorrhage is rare.[40]

Poorly differentiated squamous cell carcinoma can be confused histologically with rhabdomyosarcoma, melanoma, large cell lymphoma, SNEC, and anaplastic plasmacytoma.[41] As mentioned, immunohistochemistry can confirm the diagnosis (Table 6-1).

On plain films, all patients with paranasal sinus carcinoma have a soft-tissue sinus mass, and 70% to 90% have evidence of bone destruction (Fig. 6-18).[35, 42] The primary reason to perform sectional imaging on these patients is to

better visualize the extent of spread beyond the sinus cavity. On contrast-enhanced CT, carcinomas have a variable but slight enhancement. On MR imaging, these tumors have an intermediate T1-weighted and a slightly higher T2-weighted signal intensity. Carcinomas also enhance with contrast. Sinus carcinomas are fairly homogeneous; however, larger tumors may have areas of necrosis and hemorrhage (Figs. 6-5 and 6-19 to 6-37). The characteristic imaging feature of these carcinomas is their strong tendency to destroy bone aggressively, regardless of tumor differentiation. Bone remodeling is uncommon. Usually the area of bone destruction is substantial compared with the size of the soft-tissue tumor mass. However, the imaging findings are not specific.[43]

Basaloid squamous carcinoma refers to an aggressive, poorly differentiated variant of squamous carcinoma that may be confused with adenoid cystic carcinoma. We have seen a case in which there was CT and MR evidence of extensive bone destruction of the margins of the orbit, the floor of the middle cranial fossa, the right cavernous sinus, and much of the calvaria. There was considerable dural disease and tumor in the right orbit, paranasal sinuses, and scalp, as well as mucoceles of the left ethmoidal sinus with desiccated secretions (Fig. 6-36).[44]

Adenocarcinoma (Intestinal-Type Adenocarcinoma)

Approximately 10% of all sinonasal tumors are of glandular origin.[13] Sinonasal adenocarcinomas can be classified as either minor salivary gland tumors (e.g., adenoid cystic carcinomas, mucoepidermoid carcinomas, acinic cell carcinomas, and benign and malignant pleomor-

FIGURE 6-20 Coronal CT scan shows a destructive lesion of the left ethmoid sinus that has extended into the orbit. This patient had a squamous cell carcinoma.

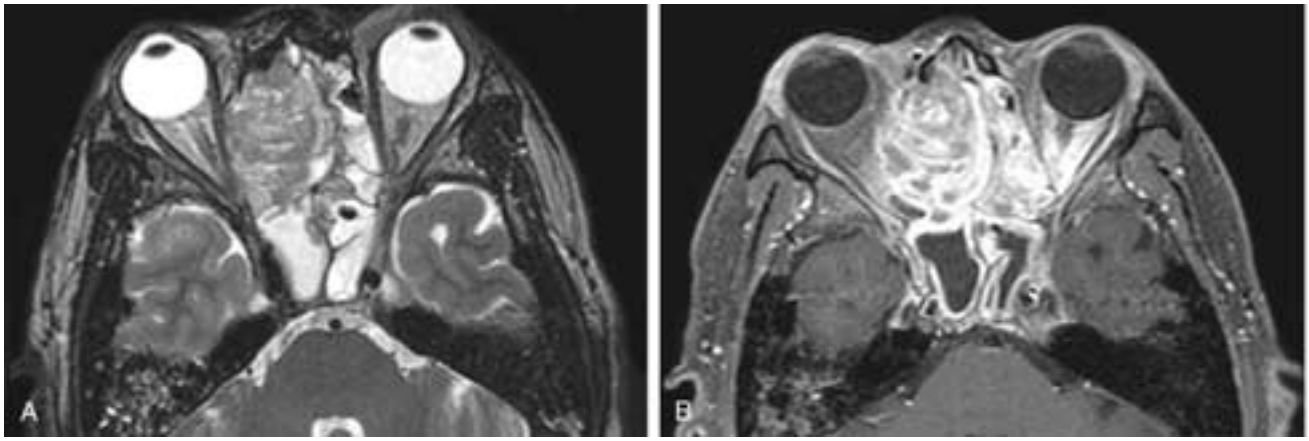
FIGURE 6-31 Axial (**A**) and coronal (**B**) T1-weighted, fat-suppressed, contrast-enhanced MR images show a large tumor in the right ethmoid complex with extension into the orbit. The medial rectus muscle has been invaded, and the globe is laterally displaced and flattened by the tumor. In addition, in **B**, dural enhancement is seen (*arrow*), indicating tumor invasion. This patient had a squamous cell carcinoma.

hardwood and shoe industries and in people who use certain carcinogenic snuffs, particularly Bantus.[45, 46] Workers exposed to wood dust have an almost 900 times greater relative risk of developing adenocarcinoma and a 20 times greater relative risk of developing squamous carcinoma.[47, 48] ITAC can be classified as either low-grade or high-grade tumors. The papillary variant is invariably associated with low-grade cytology (grade I) and has a distinctly favorable prognosis (Fig. 6-37). The high-grade colonic or signet cell types especially resemble colonic and gastric carcinomas. In these cases, it is wise to rule out metastases from these gastrointestinal sites. Such an event is rare; only 6% of all metastases to the sinonasal cavities are from primary gastrointestinal tract tumors (the most common tumors that metastasize to the head and neck are tumors of the kidney, lung, breast, testis, and gastrointestinal tract).[13, 49] Patients with sporadic ITAC tend to have shorter survival times than those with occupational exposure–related tumors. The reason for this is related to the initial tumor stage at the time of discovery. Sporadic tumors, not associated with inhaled promoters, are more likely to occur in the maxillary sinus. By contrast, occupational exposure–associated ITAC are more likely to occur in the nasal cavity and ethmoids. The maxillary sinus tumors are more likely to become symptomatic and to be diagnosed at an advanced stage, unlike the nasal cavity and ethmoid tumors, which may become symptomatic before they invade local structures.[47, 48]



VIEW IMAGE

FIGURE 6-32 Axial T2-weighted (**A**) and T1-weighted, fat-suppressed, contrast-enhanced MR images show a destructive mass in the right ethmoid complex and right orbit. Tumor extends into the left ethmoid complex. In **B**, there is poor separation of the tumor and any obstructed secretions in the left ethmoid cells. However, in **A**, this distinction is clear. There was no invasion of the left orbit. The sphenoid sinuses were obstructed. This patient had a squamous cell carcinoma.

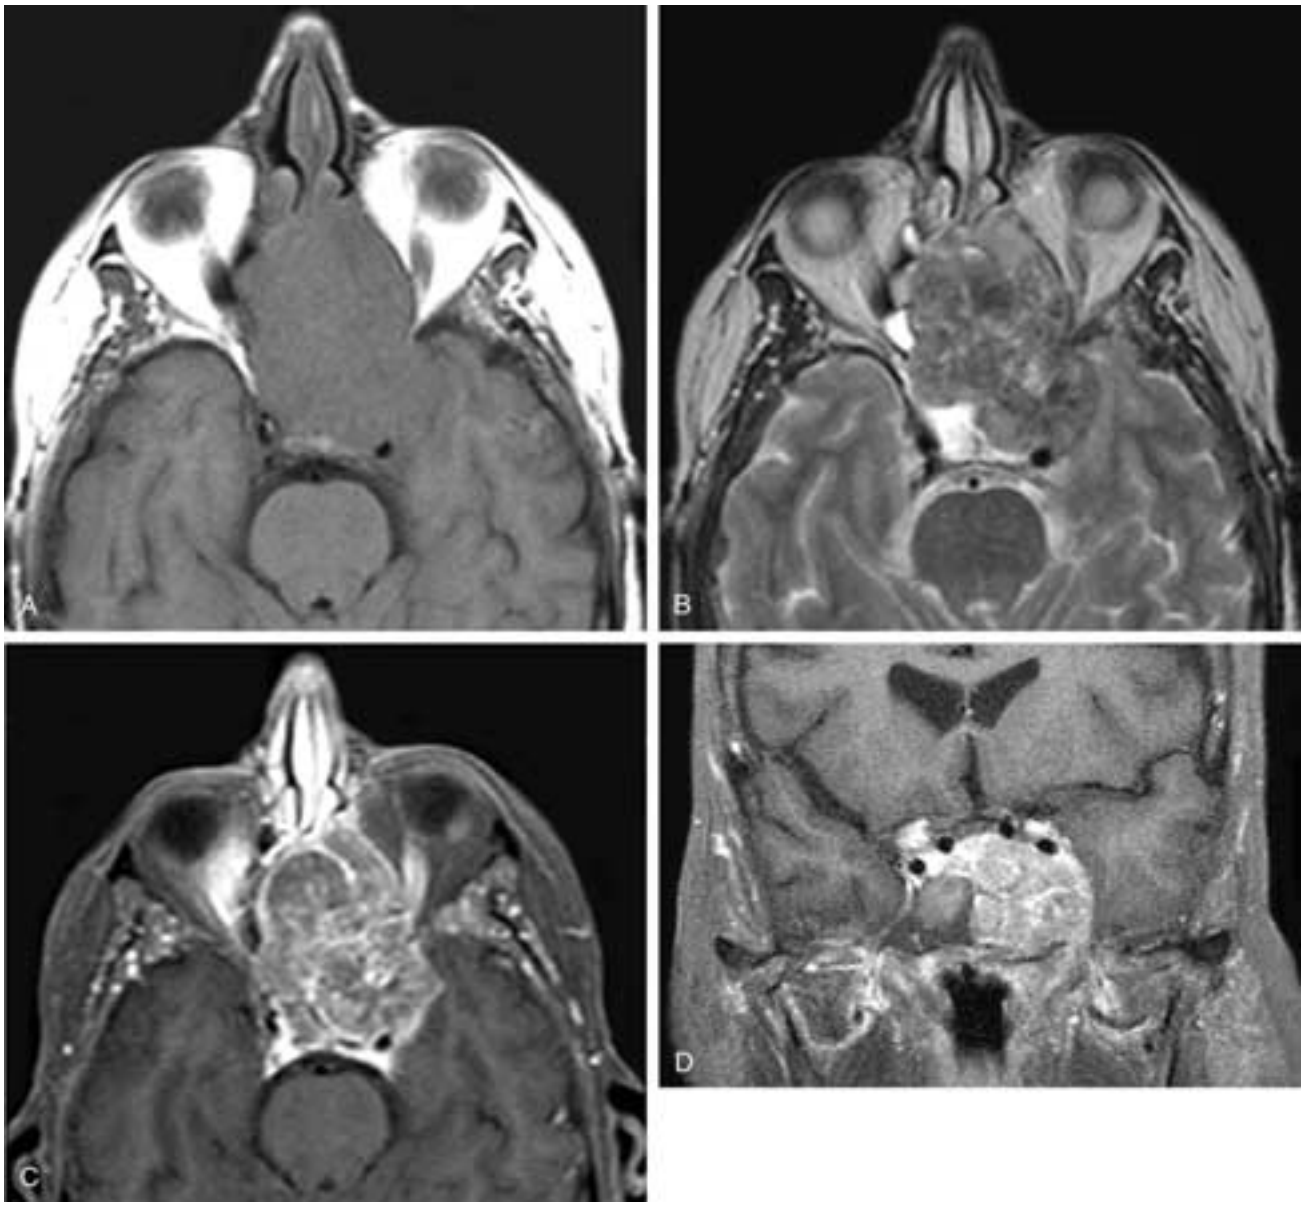
The imaging characteristics of these tumors are nonspecific and are indistinguishable from those of squamous cell carcinoma.

Salivary Tumors

Adenoid Cystic Carcinoma

Salivary gland tumors can arise anywhere within the sinonasal cavities, but most commonly arise in the palate and then extend into the nasal fossae and paranasal sinuses. The most common diagnoses, in order of decreasing frequency, include adenoid cystic carcinoma, pleomorphic adenoma, mucoepidermoid carcinoma, adenocarcinoma not otherwise specified (NOS), acinic cell carcinoma, carcinoma ex-pleomorphic adenoma, and oncocytoma.[50]

Adenoid cystic carcinomas (ACC) account for about 35% of minor salivary gland tumors.[51] Of the primary sinonasal lesions, 47% arise in the maxillary sinuses, 32% involve the nasal fossae, 7% reside in the ethmoidal sinuses, 3% occur in the sphenoidal sinuses, and 2% are found in the frontal sinuses.[13] ACC usually arise in Caucasians between 30 and 60 years of age, although these neoplasms have been reported in an age range of 4 days to 86 years. Symptoms last an average of 5 years and relate to the mass effect and neural involvement of the tumor. A dull pain signals



VIEW IMAGE

FIGURE 6-33 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images show a destructive mass in the ethmoid sinuses, nasal fossae, and left cavernous sinus. The tumor has also broken into the left orbit. Note that in **B** there are obstructed secretions (high signal intensity) in the few remaining left ethmoid and sphenoid sinuses. In **C**, the tumor extension into the cavernous sinus and left temporal lobe is better seen. This is confirmed in **D**, a coronal T1-weighted, fat-suppressed, contrast-enhanced MR image. This patient had a squamous cell carcinoma.

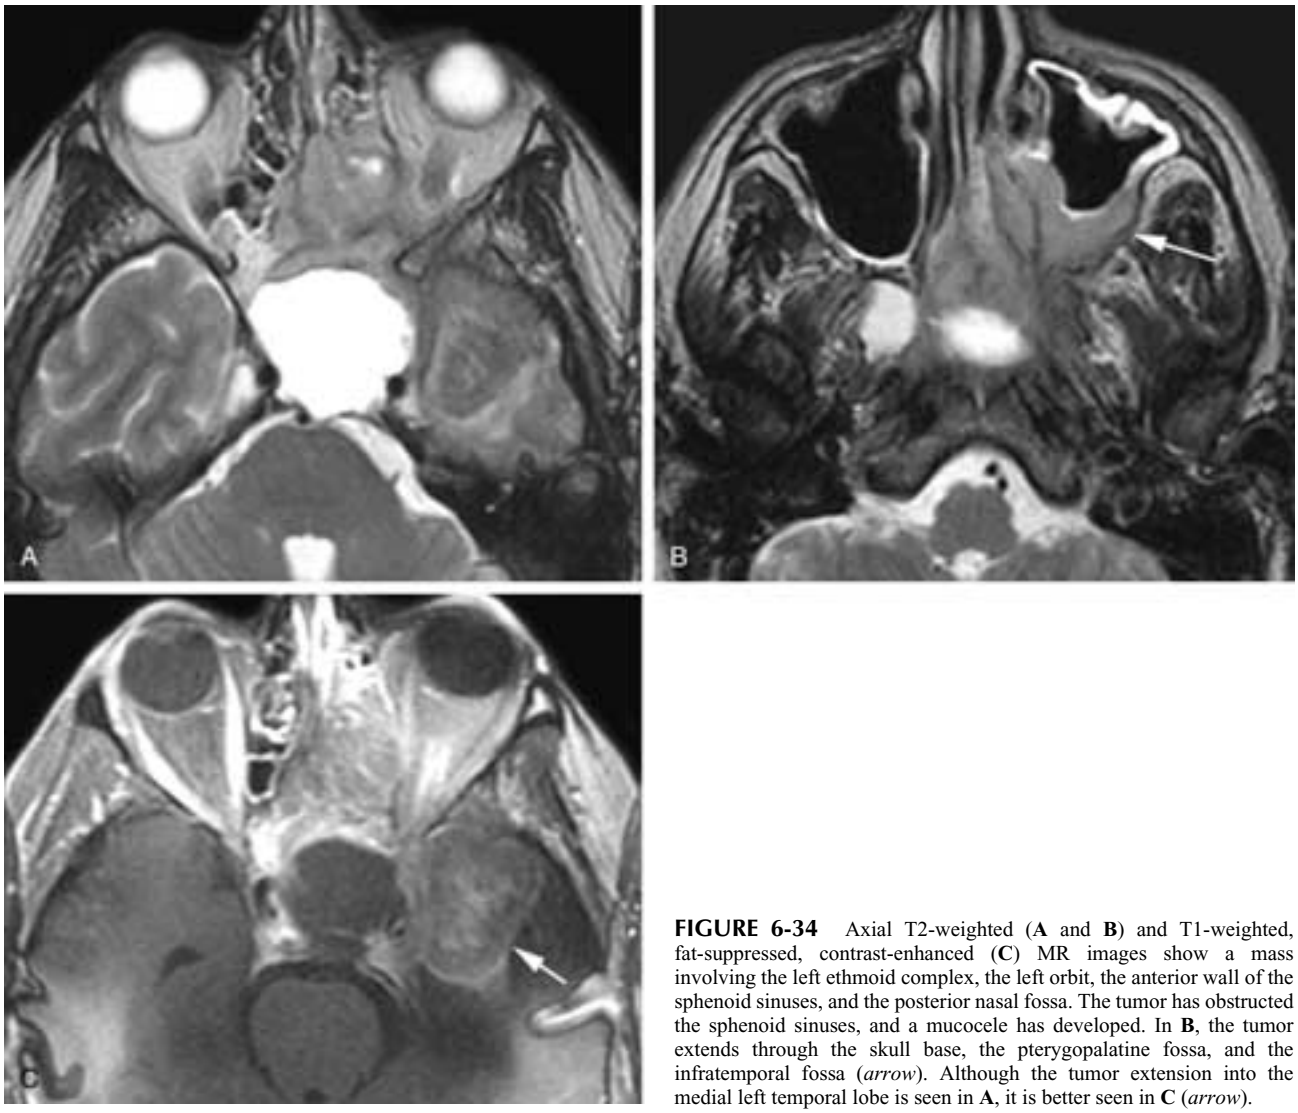

FIGURE 6-34 Axial T2-weighted (**A** and **B**) and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images show a mass involving the left ethmoid complex, the left orbit, the anterior wall of the sphenoid sinuses, and the posterior nasal fossa. The tumor has obstructed the sphenoid sinuses, and a mucocele has developed. In **B**, the tumor extends through the skull base, the pterygopalatine fossa, and the infratemporal fossa (*arrow*). Although the tumor extension into the medial left temporal lobe is seen in **A**, it is better seen in **C** (*arrow*).

VIEW IMAGE

perineural tumor invasion, which is characteristic of this tumor (see Chapter 13).

Histologically, ACC is composed of basaloid epithelial cells and myoepithelial cells. ACC forms three different architectural patterns: tubular, cribriform, and solid, with elaboration of a basement membrane and a collagenous matrix (Fig. 6-38). ACC that is predominantly tubular is considered well differentiated. If 30% or more is composed of cribriform patterns, it is classified as moderately differentiated. A poorly differentiated ACC is composed of 30% or more of the solid pattern. A temporal progression of patterns (grades) may be observed.[52]

''Skip lesions'' within nerves are known to occur; thus, negative surgical margins have little prognostic significance. The local postsurgical recurrence rate is 62% within 1 year and 67% to 93% within 5 years.[13] The local recurrence rate for ACC is highest in the sinonasal tract (63%). While the rate of local recurrence is highest within the first 5 years, a significant number of patients develop locoregional recurrence after 10, 15, and 20 years. The 5-, 10-, and 15-year survival rates for 36 patients with sinonasal ACC (treated

FIGURE 6-36 Coronal contrast-enhanced CT scan (**A**) and coronal T1-weighted, fat-suppressed, contrast-enhanced MR image (**B**) show a highly destructive tumor involving the nasal cavity, the right ethmoid and maxillary sinuses, the orbit, the right calvaria, dura, brain, and scalp. This highly aggressive tumor growth would be unusual for a typical squamous cell carcinoma. This patient had an adenosquamous carcinoma.

between 1962 and 1985) were 70%, 55%, and 55%.[53] Another report of 24 patients with sinonasal ACC (treated between 1962 and 1985) had similar survival rates at 5, 10, and 15 years (82%, 55%, and 43%).[54] As a result, 5-year survival data may give an erroneous indication of the absolute survival rate.[55] Some authorities have stated that no matter how long these patients have a disease-free interval, they will eventually die of ACC. A solid or basaloid pattern is associated with a poorer outcome. Antral tumors have the worst prognosis; 46% of patients are alive at 5 years, but only 15% are disease free.[13] About half of the sinonasal tumors have distant metastases, primarily to the lungs, brain, cervical lymph nodes, and bone.

Wide surgical excision is the treatment of choice. ACC

are radiosensitive, but they are not curable with radiation therapy alone. Despite the fact that overall patient survival may not be affected by radiation treatment, better local tumor control may be achieved if postoperative irradiation is given.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas (MEC) rank third in frequency among sinonasal malignancies of the minor salivary glands after ACC and adenocarcinomas NOS. Most of these tumors involve the antrum and nasal cavity. Almost all minor salivary gland MEC are of the high-grade or intermediate-grade variety.[50]

Histologically, MEC is composed of epidermoid cells (squamous, keratin-producing cells), intermediate cells (large, clear, non-mucin-producing cells), and goblet or mucinous cells. Grading of MEC is more predictive when histologic features of aggression are taken into account, rather than basing grading on the relative proportion of solid, epidermoid areas to cystic, mucinous components.

The biologic activity of these high-grade and intermediate-grade lesions resembles that of the adenocarcinomas. Surgical resection with negative margins is the treatment of choice for sinonasal MEC. Adjuvant radiotherapy should be considered for inadequately resected cases. Tumor grade is a very important prognosticator for MEC, and preoperative knowledge of the tumor grade can be helpful in planning for a lymphatic dissection. While inadequately resected tumors will recur, a fully low-grade tumor acts no differently than a benign tumor; its ability to metastasize appears almost nil. There is not much data available concerning survival of patients with sinonasal MEC.

Pleomorphic Adenoma

Benign mixed tumors of the sinonasal cavities are rare; most lesions occur within the nasal fossa. Usually they arise from the nasal septum, although one-fifth of the cases originate from the lateral nasal wall. The nasal septal location is curious because the septal submucosa is sparsely populated with minor salivary glands compared with the remainder of the sinonasal tract. A series of 41 cases of nasal cavity pleomorphic adenomas revealed that 90% of the cases originated from the septum and 10% (4 cases) arose in the lateral nasal wall.[56] The second most common site of origin is the maxillary sinus. Overall, pleomorphic adenoma is statistically the third most common minor salivary gland neoplasm.

Histologically, pleomorphic adenomas consist of epithelial and myoepithelial cells. The epithelial component produces ductal and glandular patterns, solid areas, and commonly undergoes squamous metaplasia. The myoepithelial component produces the abundant chondroid and myoid matrix so typical of these tumors (Fig. 6-39).

Intranasal and paranasal pleomorphic tumors are more cellular than their major salivary gland counterparts, and often the minor salivary gland lesions consist almost entirely of epithelial cells with little or no mesenchymal stroma.[55] Wide surgical excision usually prevents recurrences; however, recurrence of the tumor may be delayed well beyond the traditional 5-year period. Malignant change in a sinonasal pleomorphic adenoma is rare.[57] Benign metastasizing pleomorphic adenoma, or metastasizing pleomorphic adenoma, is an infrequent tumor that metastasizes, despite benign histology, usually to the lungs and soft tissues. A benign metastasizing nasal septal pleomorphic adenoma reportedly spread to an ipsilateral submandibular node.[56, 58]

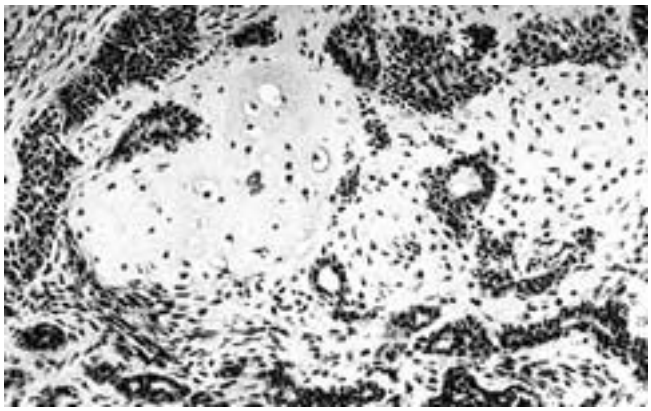

FIGURE 6-39 Pleomorphic adenoma: Glandular ductal elements are interspersed with a mesenchyme-like matrix produced by myoepithelial cells. In the center, a chondroid matrix is seen.

VIEW IMAGE

On imaging of salivary tumors, typically, pleomorphic adenomas remodel bone. Often, the nasal tumors develop as a spherical mass rather than the more typical polypoid lesion associated with most other tumors. When such a spherical configuration is seen, either a salivary gland tumor or a rare schwannoma should be considered in the imaging differential diagnosis. On CT, the less cellular salivary tumors may appear nonhomogeneous because of mesenchymal stroma, cystic degeneration, necrosis, or serous and mucous collections.[50] The highly cellular tumor tends to have a homogeneous appearance and may cause some bone erosion. On MR imaging, these tumors tend to have an intermediate signal intensity on T1-weighted images. The T2-weighted signal intensity depends on the cellularity of the neoplasm; highly cellular types usually have an intermediate signal intensity, while the stromal or less cellular variety have a high T2-weighted signal intensity (Figs. 6-40 to 6-53).[59]

The imaging characteristics of malignant pleomorphic tumors are nonspecific and are similar to those of SCC. Occasionally, they may have grossly less invasive margins on imaging than an SCC. Although this may allow an imaging diagnosis to be suggested, it is not a sufficiently reliable finding to truly differentiate these lesions.

Epithelial-Myoepithelial Carcinoma

Epithelial-myoepithelial carcinoma is an uncommon, low-grade epithelial neoplasm composed of variable proportions of ductal cells and large, clear-staining myoepithelial cells arranged around the periphery of the ducts. About 120 cases have been reported in the world literature, most of which were located in salivary glands, especially the parotid gland. A few cases have occurred in unusual locations such as the breast, lacrimal gland, nose, paranasal sinus, trachea, bronchus, and lung. A case was reported in the nasal cavity with extension to the nasopharynx. The recurrence and metastatic rates of epithelial-myoepithelial carcinoma varied from 35% to 50% and from 8.1% to 25%, respectively, for all sites.[60]

BENIGN AND MALIGNANT NEUROECTODERMAL, NEURONAL, NERVE SHEATH, AND CENTRAL NERVOUS SYSTEM TUMORS

Paraganglioma

Primary paragangliomas in the sinonasal tract are extraordinarily rare. The diagnosis of a paraganglioma in this region almost always represents a large glomus jugulare tumor that has usually extended into the sphenoid and ethmoid sinuses (Fig. 6-54).[61, 62] However, at least two cases of sinonasal paraganglioma have been reported.[63, 64] Histologically, paragangliomas are composed of nests of epithelioid, neuroendrocrine cells ensheathed by Schwannian sustentacular cells.

Treatment may include surgery and radiotherapy. In one case, 22 years later the tumor recurred and showed rapid

growth due to malignant transformation that may have been related to the radiotherapy.[63]

On imaging, these tumors are usually expansile, enhanced, and may have vascular signal voids on MR imaging. These lesions are discussed in more detail in Chapter 39. When a primary paraganglioma is encountered, it is more likely that the true diagnosis is a well-differentiated sinonasal neuroendocrine carcinoma.

Olfactory Neuroblastoma

Olfactory neuroblastoma (ONB) (historically referred to as esthesioneuroblastoma) is a neural crest–derived neoplasm arising from the olfactory mucosa in the superior nasal fossa. It occurs with a bimodal age distribution, peaking in the second and sixth decades, and representing 16.8% and 22.8% of all sinonasal tumors for these age groups, respectively. However, the age of these patients ranges from 3 to 88 years.[65, 66] ONB usually presents as a solitary soft-tissue nasal polyp that may bleed profusely on biopsy. It may also occur as a bilateral nasal mass; this usually happens in medically neglected patients.

Histologically, ONB is composed of small, relatively bland round malignant cells with scanty cytoplasm. A fibrillary background is characteristic of ONB, and ultrastructurally corresponds to neuronal processes formed by the most differentiated tumor cells. Groups of tumor cells that are centripetally aligned around tangles of neurofibrillary processes appear by light microscopy as Homer-Wright rosettes. An abundance of these rosettes indicates a well-differentiated tumor. Flexner-Wintersteiner rosettes represent evidence of true olfactory differentiation and are seen as gland-like structures formed by columnar or cuboidal tumor cells.

The term *ganglioneuroblastoma* refers to ganglionic maturation within a neuroblastoma. This may be seen at initial tumor presentation (referred to as differentiating neuroblastoma) and is associated with an improved prognosis. Ganglionic maturation may also be seen after a chemotherapeutic response of neuroblastoma. This type of de novo or secondary ganglionic differentiation is not seen in ONB. This may reflect inherent distinctions between olfactory neuroepithelium (a direct extension from CNS neurons) and the postsynaptic sympathetic neuroblasts that give rise to neuroblastomas.

Hyams introduced a four-tier grading system of ONB: grade I ONB represents the most differentiated tumor, with rosette formation and no pleomorphism, mitotic figures, or necrosis, while grade IV ONB reveals no histologic evidence of neuronal/neuroendocrine differentiation, and the findings of pleomorphism, mitotic activity, and necrosis are present. Hyams was able to correlate tumor grade with prognosis. More recently, the question has been raised if grade IV ONB tumors are actually not ONB, but better classified as sinonasal neuroendocrine carcinomas (see below). Additionally, the less differentiated an ONB appears to be, the greater the need to rule out other diagnoses such as undifferentiated carcinoma (sinonasal undifferentiated carcinoma), large cell lymphoma, melanoma, extramedullary plasmacytoma, and embryonal rhabdomyosarcoma. Immunohistochemistry has become the standard adjunctive test to resolve these issues.

The Kadish staging system is a clinically based staging system for sinonasal tumors. Those lesions confined to the nasal cavity are stage A, those with disease in the nasal cavity and one or more paranasal sinuses are stage B, and those with disease extending beyond the nasal cavity and paranasal sinuses are stage C.[67] Both the Hyams grading system and the Kadish staging system can be used as independent predictors of outcome.[68] In the Kadish staging system, the 5-year survival rates for patients with stage A, B, and C tumors are 75%, 68%, and 41.2% respectively.[66, 67] Craniofacial resection can be curative for up to 90% of patients, as this approach addresses microscopic disease at the cribriform plate and in the olfactory bulbs, which are below the detection threshold of current radiographic imaging.[69] By contrast, a recurrence rate of nearly 50% can be seen after an extended lateral rhinotomy for stage A and stage B patients. The 5-year survival rate for all patients is 69%.[70] A more recent report indicates 80.4% disease-free survival at 8 years.[71] When survival is stratified for tumor grade, the 5-year disease-free survival for patients with low-grade and high-grade tumors is 80% and 40%, respectively.[72] Locoregional and distant metastasis occurs in up to 38% of patients.[73] Late recurrences or metastatic disease can occur up to two decades after initial presentation. Negative prognostic factors include female sex, age over 50 years at presentation, tumor recurrence, metastasis, high tumor grade, and Kadish stage C at presentation.[72]

Preoperative imaging is crucial to tumor mapping and planning the extent of surgery. On CT, ONBs usually are homogeneous, enhancing masses that primarily remodel bone. They commonly extend into the ipsilateral ethmoid and maxillary sinuses and rarely involve the sphenoid sinuses. When large, they can extend to involve both sides of the nasal cavity and the paranasal sinuses. Gross calcifications can occur within the tumor mass, and they can also be seen histologically.[74] On MR imaging these tumors have an intermediate signal intensity on all imaging sequences, with the T2-weighted signal intensity being higher.[75] They also enhance with contrast (Figs. 6-55 to 6-61). When imaging these tumors, the radiologist must carefully evaluate the floor of the anterior cranial fossa for tumor extension into this region. If intracranial tumor extension is seen, the imager should attempt to distinguish between tumor that remains extraaxial (with only dural disease) and tumor that has invaded brain, as such a differentiation alters surgery. In some of the larger tumors that have intracranial extension, peripheral tumor cysts can occur at the margins of the intracranial mass. These cysts have their broadest base on the tumor, and when seen, they strongly suggest the imaging diagnosis of this tumor.[76]

Sinonasal Neuroendocrine Carcinoma and Sinonasal Undifferentiated Carcinoma

Sinonasal neuroendocrine carcinoma (SNEC) and sinonasal undifferentiated carcinoma (SNUC) were first described in the 1980s, but remarkably few series of either have been reported. SNEC and SNUC can be conceptualized

as being part of a spectrum of neuroendocrine-type tumors, with ONB representing the most specialized and differentiated neuroendocrine tumors and SNUC having dubious or weak neuroendocrine qualities.

SNEC was first proposed in 1982, when it became clear that some tumors were less differentiated than ONB but still retained neuroendocrine features.[77] Many had been buried in the literature as oat cell carcinoma, atypical carcinoid, malignant paraganglioma, or anaplastic or undifferentiated carcinoma. SNEC is defined as a malignant neoplasm with evidence of neurosecretory granules. Lacking evidence of a neurofibrillary background by light microscopy, as is seen in ONB, it is less differentiated and more ''carcinomatous'' than ONB. The term *sinonasal undifferentiated carcinoma* was first coined by Frierson and colleagues to define a group of sinonasal tumors with no obvious differentiation that

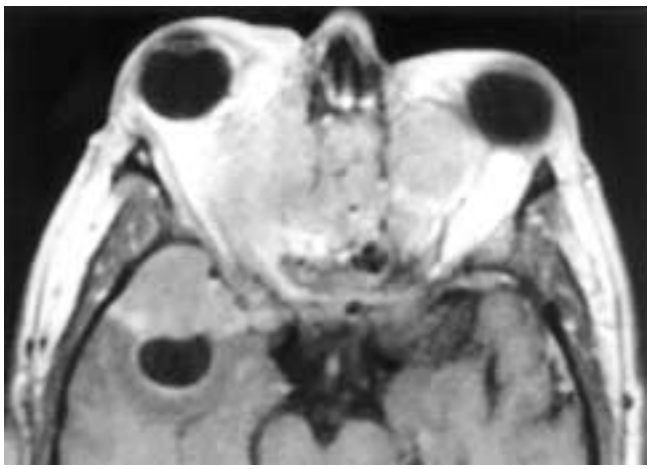
were united by their obviously aggressive clinical course.[78] These tumors were previously diagnosed as ''anaplastic'' or ''undifferentiated.'' A possible etiologic relationship to heavy metal exposure, coal mining, the chemical industry, and shoemaking has been reported.[78, 79]

Few demographic or prognostic comparisons can be made between SNUC, SNEC, and ONB due to their rarity. In the group reported by Silva et al., 20 patients diagnosed with SNEC were compared with 9 patients with ONB.[77] The mean age of the patients with SNEC was 50, while that of the patients with ONB was 20. However, other studies of larger groups of ONB patients reflect the true bimodal age peak of ONB, with a median age of 49.[78] Gallo et al. found that the mean age of patients with SNUC was 56.7 for men and 68 for women.[79] Most cases of SNEC/SNUC occur in the same sites as ONB (superior nasal cavity, superior turbinates, ethmoids). Presenting symptoms relate to a sinonasal tumor: nasal obstruction, epistaxis, decreased visual acuity, diplopia, and pain.

The radiographic findings of SNEC and SNUC are usually indistinguishable from those of SCC: an aggressive soft-tissue mass that erodes and invades adjacent bone rather than remodeling it (Fig. 6-62). In contrast, the CT and MR imaging findings of ONB are usually those of an expansive mass. In smaller SNEC lesions, the mass is usually polypoid and confined to one nasal fossa, often with involvement of a surrounding ethmoid or medial maxillary sinus margin. Larger lesions may extend into adjacent structures such as the orbit and the cranium.



VIEW IMAGE

FIGURE 6-61 Axial T1-weighted, contrast-enhanced MR image on a patient who previously had a craniofacial resection for an olfactory neuroblastoma. Histologically, SNEC is composed of cells with fine ''salt and pepper'' chromatin, with a variable amount of cytoplasm. Architecturally, classic neuroendocrine patterns can be seen: nesting, organoid, trabecular, and/or a ribboning pattern. Glandular-type differentiation may be seen. SNUC is composed of cells with little cytoplasm and large nuclei. No histologic tendency toward neuroendocrine architecture is seen. However, SNEC/SNUC and ONB may also appear quite similar histologically; immunohistochemistry is crucial for sorting out these entities.

In terms of clinical course, the prognosis of SNEC and SNUC seems to be related to the stage at the time of diagnosis. Silva et al. reported 5- and 7-year survival rates of 100% and 88%, respectively, for his cohort of 20 patients with SNEC but noted a propensity for early metastases and local recurrence. They reported evidence of metastases to lymph nodes, brain, and spine in all cases of theirs in which metastatic disease was present, except for one where the lungs and femur were involved.[77] Similarly, in our study, 7 of the 10 patients developed metastatic disease, either to cervical lymph nodes (2 cases), pelvis (2 cases), thoracic spine (1 case), brain (1 case), or skeletal bones (1 case). In our study, two patients with SNEC died of disease at 14 and 41 months. The other two patients in our series with SNEC were alive, with no evidence of disease, at 31 and 108 months. Outcomes for SNUC have been reported to be generally poor.

Malignant Melanoma

Melanocytes in the sinonasal tract migrate from the neural crest during embryonic development.[13] The etiology of sinonasal melanomas is unknown, but they represent less than 3.6% of sinonasal neoplasms. Less than 2.5% of all malignant melanomas occur in the sinonasal cavities. These melanomas are two or three times more common in the nose than in the sinuses and most frequently arise from the nasal septum.[80, 81] Occasionally, they develop around the inferior and middle turbinates. The antrum is involved in 80% of paranasal sinus cases, usually in conjunction with the nasal cavity. Rare cases develop in the ethmoid sinuses. The frontal and sphenoid sinuses are virtually never involved as primary sites.[13, 80–82] Sinonasal melanomas generally develop in patients 50 to 70 years of age. The most common complaints are nasal obstruction and epistaxis, with pain occurring as an initial complaint in only 7% to 16% of patients.[13, 80, 81] Satellite tumor nodules are common.

Wide local surgical excision with or without postoperative radiation therapy is the treatment of choice. Up to 40% of patients with sinonasal melanomas present with positive neck nodes.[83, 84] Up to 65% of patients with melanoma have a local recurrence or metastases within the first year after surgery. Metastatic disease usually follows local recurrence.

Metastases tend to affect the lungs, lymph nodes, brain, adrenal glands, liver, and skin. Treatment of recurrences yields surprisingly good results.[13] The median survival time is 18 to 34 months.[83, 84] Occasional cases may be mysteriously dormant for up to a decade before there is an explosive recurrence. Nasal cavity melanomas have a better prognosis than tumors originating in the paranasal sinuses; the average survival time of all of these patients is 2 to 3 years, and the 10-year survival rate is 0.5%. The differential diagnosis of melanoma includes undifferentiated carcinoma, lymphoma, embryonal rhabdomyosarcoma, ONB, and extramedullary plasmacytoma.[41]

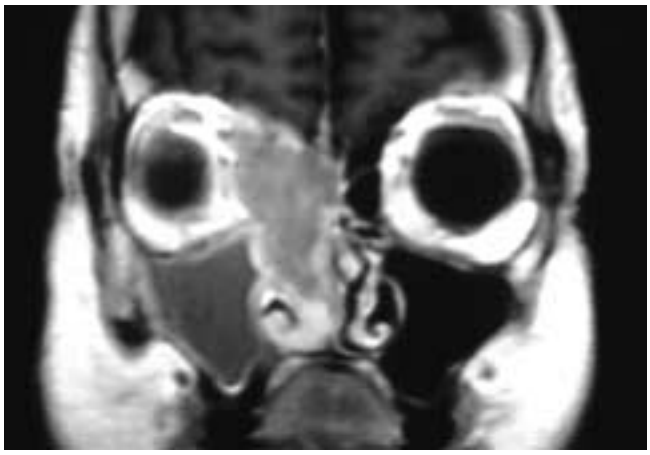

FIGURE 6-63 Coronal T1-weighted, contrast-enhanced MR image (on the same patient as in Fig. 6-8) shows an enhancing mass in the right ethmoid complex and nasal fossa. The tumor has broken into the right orbit but has a smooth interface with the orbital fat. The right antrum is obstructed by the mass. This patient had a melanoma.

VIEW IMAGE

Melanomas tend to remodel bone, although elements of frank bone erosion also may be present. Because of their rich vascular network, melanomas enhance well on contrast-enhanced CT and MR scans, and their MR imaging appearance is usually that of a homogeneous mass of intermediate signal intensity on all imaging sequences. However, some melanomas have high T1-weighted signal intensity primarily because of the presence of hemorrhage and, to a lesser degree, paramagnetic melanin (Figs. 6-8 and 6-63 to 6-67). These melanomas may have a deceptively noninvasive border on imaging, suggesting that they are low-grade lesions. Such lesions emphasize the lack of correlation between the imaging evidence of a noninvasive

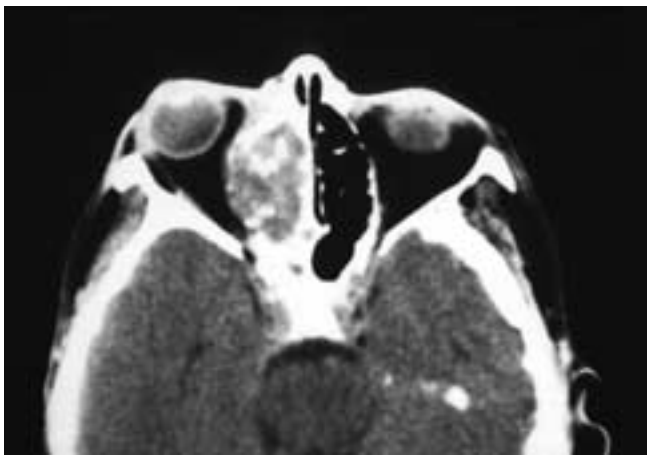

FIGURE 6-64 Axial CT scan shows an expansile mass in the right ethmoid complex that is bulging into the right orbit. Most of the lamina papyracea and ethmoid septations are destroyed or thinned. Radiodensities within the mass were residual pieces of bone. This patient had a melanoma.

tumor margin and the biologic aggressiveness of the tumor. Most of these tumors occur in the nasal fossa. However, a rare case was reported to arise in the frontal sinus in a patient who presented with forehead swelling and progressive confusion.[85]

Pathologically, melanomas are known as the ''great mimickers,'' as they produce myriad patterns composed of varying cell types. Melanomas may be epithelioid, sarcomatoid, plasmacytoid, or clear cell. Pink nucleoli, intranuclear holes, and cytoplasmic melanin can be seen (Fig. 6-68). The diagnosis can be confirmed immunohistochemically by the expression of S100 and HMB-45.

Melanotic Neuroectodermal Tumor of Infancy

This is an extremely rare neuroectodermal tumor that occurs almost exclusively prior to the age of 1 year. It is a rapidly growing soft-tissue mass of either the upper or lower jaws, the CNS, or the orbit. The anterior maxilla is the most common site, accounting for 71% of all cases. Bone invasion may occur. Histologically, these tumors are distinctive, with tubular or alveolar formations of large melanin-containing cells around nests of smaller neuroblastic cells. A series of 20 cases has been reported by Kapadia and colleagues, 5 of 12 (45%) patients with follow-up developed recurrence within 4 months of diagnosis, but none metastasized.[87] Treatment is usually local excision. Only two or three malignant cases have been reported, with metastases to lymph nodes, liver, bones, adrenal glands, and soft tissues.[65, 86, 87]

Primitive Neuroectodermal Tumor and Ewing's Sarcoma

Ewing's sarcoma (ES) is a highly malignant small, round cell tumor that accounts for 5% to 10% of all primary bone malignancies. About 60% of cases occur in the lower extremities and pelvis.[88] Almost 90% of patients are between 5 and 30 years of age at diagnosis. Only 1% to 4% of all ES occur in the bone and soft tissue of the head and neck, most commonly the mandible, followed by the maxilla, calvaria, and cervical vertebrae.[89] ES rarely arises from the nasal cavity/paranasal sinuses and has been seen as a complication of radiation therapy for retinoblastoma.[90–92]

Primitive neuroectodermal tumor (PNET) is a malignancy of childhood and early adulthood that is closely related to ES. PNET occurs most commonly as a soft tumor of the lower truck or lower extremities. Association with a major nerve trunk has been seen in one third of the cases. PNET does occur in the head and neck, usually in the sinonasal cavities (Fig. 6-69) and has also been reported in patients who have survived retinoblastoma.[93–96] Patients with ES/PNET typically present with pain and localized swelling.

Radiographically with ES, a destructive soft-tissue lesion is seen with a typical ''onion skin'' type of periosteal reaction. Less often with both ES and PNET, a ''sunburst'' type of periosteal reaction can be seen.

Pathologically, ES and PNET appear as malignant ''small blue round cell tumors'' that are relatively bland in appearance. The distinction between these two neoplasms is based on immunophenotypic and ultrastructural findings. PNET shows some evidence of neuroendocrine differentiation, such as neurosecretory granules and cellular processes by electron microscopy (EM) and evidence of expression of two or more neuroendocrine markers (this neuroendocrine differentiation is quantitatively much less than that seen in ONB). ES, on the other hand, reveals no evidence of any kind of differentiation. Both tumors are associated with chromosomal translocation (11;22) (q24;q12) that forms the fusion protein EWS/FLI-1; EWS/ERG.

The treatment of choice for ES and PNET is local excision, with radiation therapy for the incompletely excised

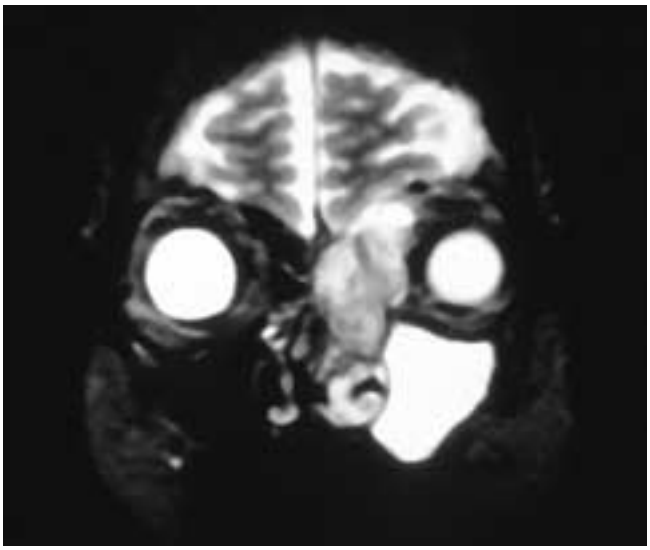

FIGURE 6-66 Coronal T2-weighted MR image shows a mass in the left ethmoid complex and nasal fossa. The tumor has extended into the left orbit and has a smooth interface with the orbital fat. The adjacent sinuses are obstructed. This patient had a melanoma.

lesions. Micrometastases, which are present in 15% to 30% of patients, are treated with chemotherapy. The 5-year survival rates have risen from less than 10% in the prechemotherapy era to the current 60% to 79%. ES recurs locally in 13% to 20% of patients (65% at postmortem), usually coinciding with the completion of chemotherapy. The tumors metastasize to the lungs (86%), skeleton (69%), pleural cavity (46%), lymph nodes (46%), dura and meninges (27%), and CNS (12%). Because of its rarity in the facial area, ES of the sinonasal cavities probably should be considered a metastasis from an infraclavicular primary tumor until proven otherwise. The significance of the distinction between ES and PNET is that PNET is somewhat more chemosensitive than ES and is associated with a longer mean survival after multimodality therapy.

Peripheral Nerve Sheath Tumors

Schwannoma

Peripheral nerve sheath tumors is the currently preferred term for benign and malignant neoplasms that arise from neuronal axons and/or their supporting cells (Schwann cells and fibroblasts). Confusing terminology has arisen in the literature, with many names representing the same lesion. One of the difficulties in discussing neurogenic neoplasms is that there is also controversy regarding whether nerve sheath tumors arise from Schwann cells or neuroectodermal perineural cells.[65] Today most investigators use the term *Schwann cell* to describe both of these cells. The terms *schwannoma, neurinoma, neurilemoma,* and *perineural fibroblastoma* all refer to the same tumor.[1] Peripheral nerve sheath tumors are common in the head and neck. Up to 40% of these tumors occur in head and neck sites. Only 4% of these tumors occur in the sinonasal cavities.[97–99]

A schwannoma is defined as a tumor composed entirely of nerve-supporting cells, without neuronal elements. It is a benign, encapsulated, slowly growing tumor that occurs in patients 30 to 60 years of age. It is two to four times more common in females than in males. The most common sites are the vagus nerve in the neck and the eighth cranial nerve. Only about 65 cases have been reported in the sinonasal cavities, and most of these occurred in the nasal fossa, maxillary sinuses, and ethmoidal sinuses.[1, 65, 100] In rare cases, a schwannoma can occur in the olfactory bulbs (Fig. 6-70). This is a distinctly different entity than ONB. The most common complaint is a painless mass.

Schwannomas rarely undergo malignant change. At surgery, the nerve of origin may occasionally be found to be stretched over the tumor. In these cases, the surgeon may be able to extirpate the lesion while preserving the nerve. By contrast, neurofibromas are defined as having neuronal elements as an integral part of the tumor. They appear as swellings arising directly from the nerve, and the nerve must be sacrificed to excise the lesion.[65]

Histologically, schwannomas have two major components: the Antoni A areas, characterized by a compact arrangement of elongated spindled cells, and the Antoni B areas, characterized by a loose myxoid stroma with few spindled cells. This variation is reflected in their CT appearance, which ranges from a variably enhancing homogeneous ovoid mass to a primarily cystic lesion.[101] On contrast-enhanced CT, about one third of the cases enhance more than muscle, one third have attenuation values similar to that of muscle, and one third are primarily cystic.[99] The enhancement on CT and MR images occurs presumably because of extravascular extravasation of the contrast into a poorly vascularized tumor matrix. The MR imaging characteristics of schwannomas are those of an intermediate T1-weighted and a variable T2-weighted signal intensity that reflect whether the lesion is highly cellular (intermediate signal intensity) or cystic and stromal (nonhomogeneously high signal intensity). All schwannomas are roughly ovoid shaped, noninfiltrating, bone-remodeling lesions, and any site of aggressive bone destruction should raise the possibility of a malignancy rather than a schwannoma (Figs. 6-71 to 6-74).

Neurofibroma

Neurofibroma is a benign, fairly well-circumscribed, but nonencapsulated nerve sheath tumor. Histologically, it is relatively uniform, composed of fibroblastic cells and neuronal elements within a collagenized matrix. Neurofibromas may occur as a solitary tumor or as multiple tumors. Neurofibromas, especially in a young patient, may herald the onset of other tumors with neurofibromatosis (von Recklinghausen's disease). This disease is transmitted as an autosomal dominant trait with variable penetrance. It is characterized by café au lait spots, multiple neurofibromas, and characteristic bone lesions.[102] Multiple neurofibromas are more likely to be associated with neurofibromatosis (Fig. 6-75).[99] Approximately 8% (5% to 15%) of these tumors may have malignant degeneration.[103, 104] The clinical appearance of a plexiform neurofibroma is considered pathognomonic of neurofibromatosis even in the absence of other signs. This tumor usually remains within the confines of the perineurium and resembles a ''giant nerve,'' a ''bag of worms,'' or a ''string of beads.''[65]

Neurofibromas can have a variable CT appearance, depending in part on the degree of cystic degeneration and fatty replacement present within the lesion. On contrast-enhanced CT, these tumors may enhance homogeneously, contain multiple cystic areas, or have predominantly fatty attenuation. The degree of fatty replacement within some neurofibromas is far more extensive than that ever seen in schwannomas and may at times cause the radiologist to suggest the diagnosis of lipoma. Neurofibromas remodel bone and do not cause aggressive bone destruction. They are roughly ovoid in shape and have noninvasive margins. If bone has been destroyed, the possibility of a malignant degeneration should be considered. On MR imaging they usually are nonhomogeneous tumors with overall intermediate T1-weighted and high T2-weighted signal intensities. The plexiform lesions in particular often have a fairly high T2-weighted signal intensity and have a ''bag of worms'' configuration rather than a solitary ovoid shape.

Traumatic Neuroma

Traumatic neuroma is not a true neoplasm but a reparative lesion that occurs after disruption of a peripheral nerve. If the proximal portion of the nerve cannot reestablish contact with the distal portion, the proliferating Schwann cells and axons grow haphazardly and form a traumatic neuroma. Excision with approximation of the nerve endings is the treatment of choice.[65]

Malignant Peripheral Nerve Sheath Tumor

Malignant peripheral nerve sheath tumor (MPNST), a term that has replaced *malignant schwannoma,* refers to a neuroectodermal sarcoma that is the malignant counterpart of a neurofibroma.[105] Up to half of MPNSTs occur in patients with neurofibromatosis (von Recklinghausen disease). The typical solitary MPNST occurs in adults, usually between the third and sixth decades of life. Only 9% to 14% of MPNSTs are found in the head and neck. The cranial nerves, large cervical nerves, sympathetic chain, and inferior alveolar nerve are the most commonly involved nerves. Symptoms include an enlarging mass, occasional pain, paresthesia, muscle weakness, and atrophy.[65]

Schwann cells are modified fibroblasts that produce collagen and have a spindled morphology. Some MPNSTs can then be confused histologically with fibrosarcomas.[65] Association with a nerve trunk, immunohistochemical expression of S-100, and ultrastructural evidence of redundant basement membrane and cellular processes aid in establishing the correct diagnosis. MPNSTs associated with neurofibromatosis behave more aggressively than isolated lesions. The 5-year survival rates are 15% to 30% with neurofibromatosis and 27% to 75% without it. Tumors that exceed 7 cm in size, have more than 6 mitoses per 10 high-power fields, and are located near the central body axis have a poorer prognosis. Local recurrences and hematogenous pulmonary metastases are common, whereas lymph node metastases are rare.[106] Their imaging characteristics may be similar to those of SCC (Fig. 6-63).

Granular Cell Tumor

Granular cell tumors (histologically referred to as myoblastomas) are uncommon benign tumors that are most commonly seen in the dermis and subcutis as single or multinodular lesions. In the head and neck, they occur as subcutaneous tumors of the skin of the nose, eyelids, forehead, scalp, and neck. They also may develop in the lips, floor of the mouth, lateral tongue, palate, pharynx, larynx, and trachea. Granular cell tumors rarely occur in the paranasal sinuses. Most occur in patients 35 to 40 years old. There is a general female predominance, and a disproportionate number of cases occur in African-American patients.

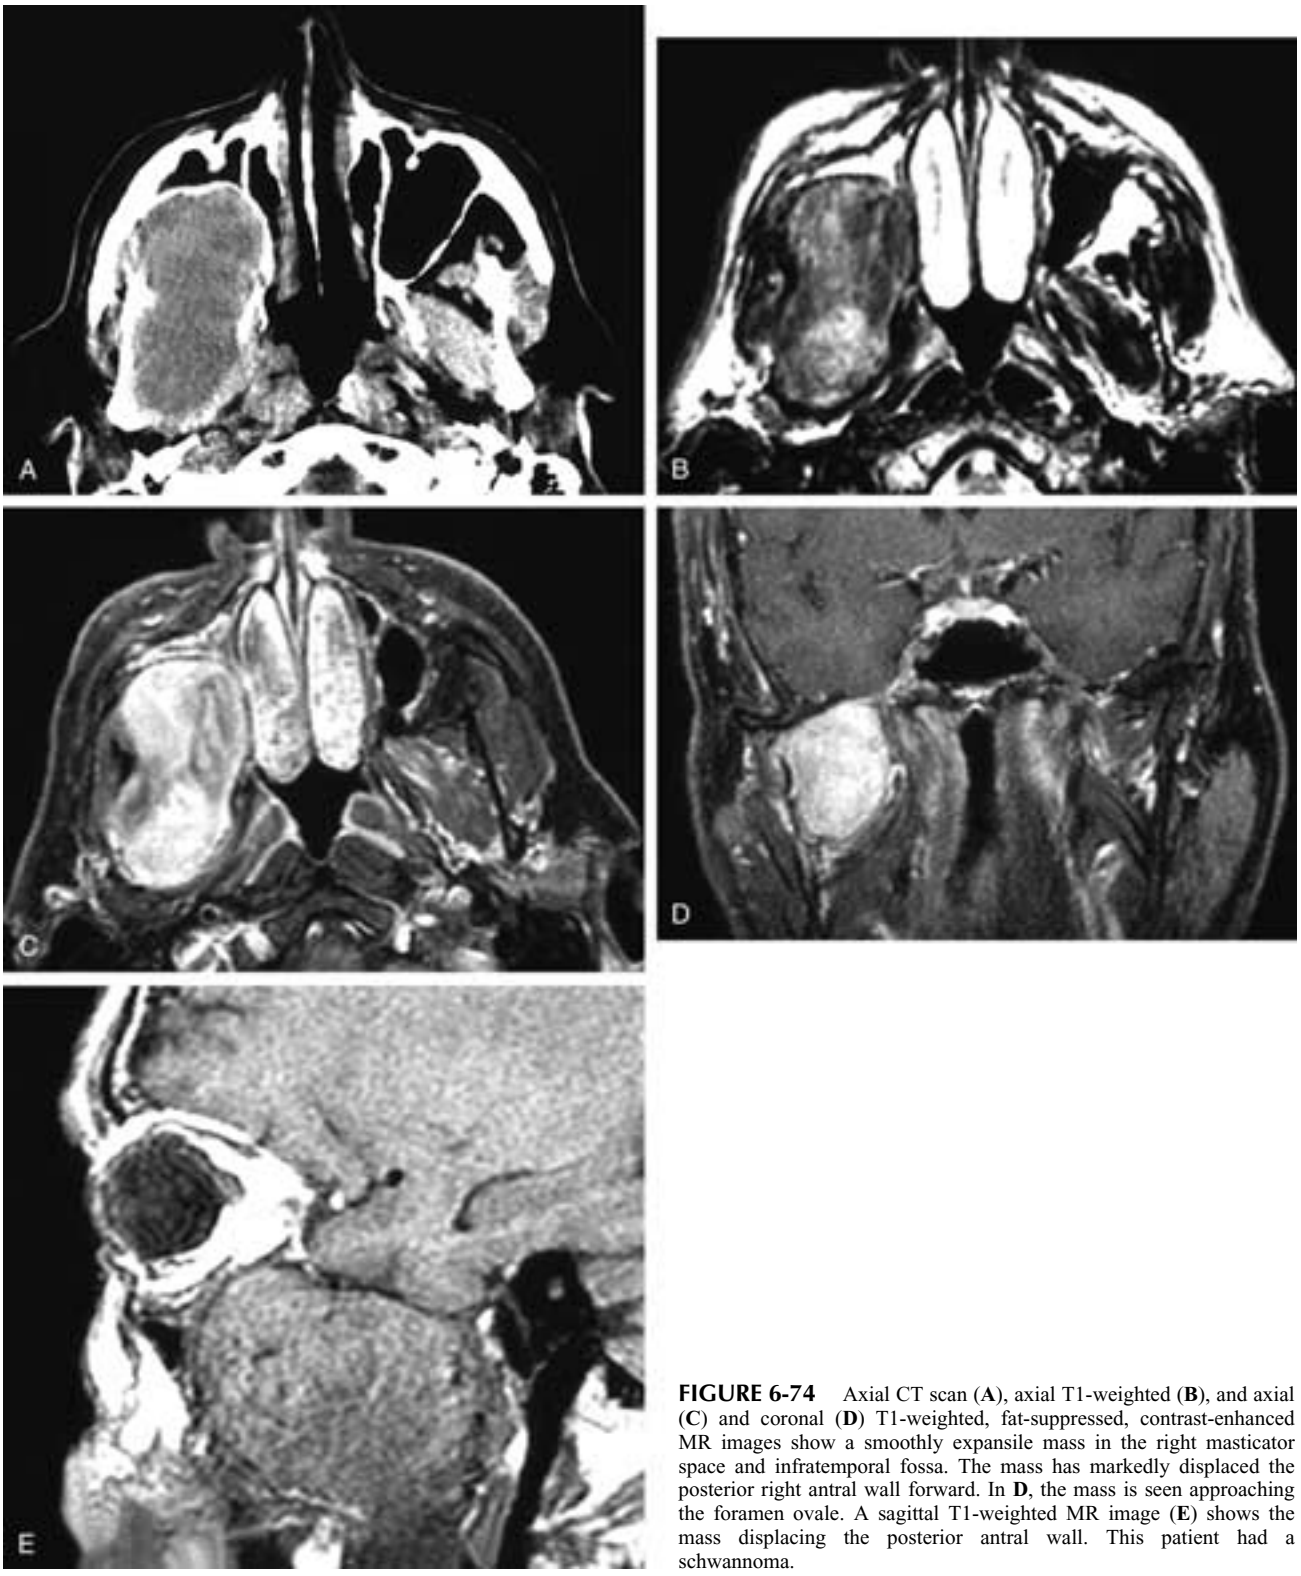

FIGURE 6-74 Axial CT scan (**A**), axial T1-weighted (**B**), and axial (**C**) and coronal (**D**) T1-weighted, fat-suppressed, contrast-enhanced MR images show a smoothly expansile mass in the right masticator space and infratemporal fossa. The mass has markedly displaced the posterior right antral wall forward. In **D**, the mass is seen approaching the foramen ovale. A sagittal T1-weighted MR image (**E**) shows the mass displacing the posterior antral wall. This patient had a schwannoma.

FIGURE 6-77 Granular cell tumor: This neoplasm is composed of bland cells with abundant granular cytoplasm and small nuclei. The granules correspond to lysosomes containing myelin.

not be present.[65] Ultrastructurally, cytoplasmic granules can be seen as autophagolysosomes containing myelin-like structures. This confirms the Schwannian lineage. Excision is curative, even for those tumors that may be incompletely excised. Rarely, malignant granular cell tumors may be encountered. Malignant granular cell tumors are either large yet histologically benign and metastatic, or they are histologically malignant and metastatic.[107] On imaging, they usually have slightly irregular margins and are located in the subcutaneous fat, deep to the skin line (Fig. 6-78).

Meningioma and Craniopharyngioma

Meningiomas are benign, slowly growing tumors arising from rests within the arachnoid villi, usually in relation to the major dural sinuses. They comprise 13% to 18% of all primary intracranial tumors and are two to four times more common in females than in males; their incidence peaks near 45 years of age.[65] These tumors can extend from or arise outside of the neuroaxis; however, this is uncommon. When meningiomas are encountered outside of the neuroaxis, about two thirds are actually direct extensions from an intracranial or intraspinous lesion.[108, 109] Primary extracranial meningiomas are quite rare, comprising less than 1% of cases.[110] Most of these extraneuroaxis meningiomas occur in the head and neck, and also have been reported in the calvarium, orbit, nose, paranasal sinuses, oral cavity, middle ear, skin of the scalp, and cervical soft tissues.[65, 111, 112] Very rarely, an extracranial meningioma might represent a metastasis from an intracranial meningioma.[113]

The imaging characteristics of these sinonasal meningiomas are those of an enhancing, expansile mass with bone remodeling. Most lesions lie in the nasal vault, and adjacent sclerotic, reactive bone may be a dominant feature. This reactive bone radiographically mimics fibrous dysplasia. If the tumor has spread extracranially, the skull base remodeling and the sinonasal tumor extension are best seen on coronal images. On MR imaging, these tumors have signal intensities similar to those of the brain on all imaging sequences. They enhance, and vascular flow voids are rarely observed (Figs. 6-79 to 6-81).

Craniopharyngioma is a rare, histologically benign, expansile intracranial neoplasm derived from retained embryonic odontogenic rests within Rathke's pouch. It occurs in children and adults as solid and cystic calcifying tumors. Histologically, these epithelial tumors resemble ameloblastomas. A case of craniopharyngioma invading the nasal cavities and paranasal sinuses was reported in a patient who presented with nasal obstruction. Imaging showed a destructive mass of the skull base with involvement of the sinonasal cavities.[114] In another report, a 7-year-old boy complained of intermittent epistaxis for several months. CT scans showed a mass in the left ethmoid sinus and

endoscopic sinus surgery removed the mass completely, which was a craniopharyngioma[115] (see also Chapter 12).

Chordoma

Chordomas are indolent, invasive tumors arising from embryonic notochord remnants representing about 1% of all primary malignant bone tumors.[116] The majority of tumors present either in the spheno-occipital (primarily clivus) area (30%) or in the sacrococcygeal area (51%). A smaller percentage may occur in other sites along the cervical or thoracic spine (19%). Rare chordomas have been reported in the ethmoid, maxilla, and mandible.[117, 118] In these cases, the tumor presumably arises in notochordal remnants that separated from the main notochord during the extreme mesodermal movements of the face that take place in early embryogenesis. These ectopic rests can be located in the paranasal sinuses.[117, 119]

There is a broad age range for chordomas of the head and neck, from the first through the eighth decades of life, with a broad peak incidence in the third to fifth decades. Presenting symptoms include visual changes, cranial nerve deficits, and headache, symptoms for the most part referable to a skull base mass.

Histologically, chordomas are composed of strands and islands of cleared epithelial cells, some of which have a characteristic ''soap bubble'' (physillifarous cells) appearance. These cells produce an abundant myxoid/chondroid-type matrix (Fig. 6-82). Therefore, the differential diagnosis

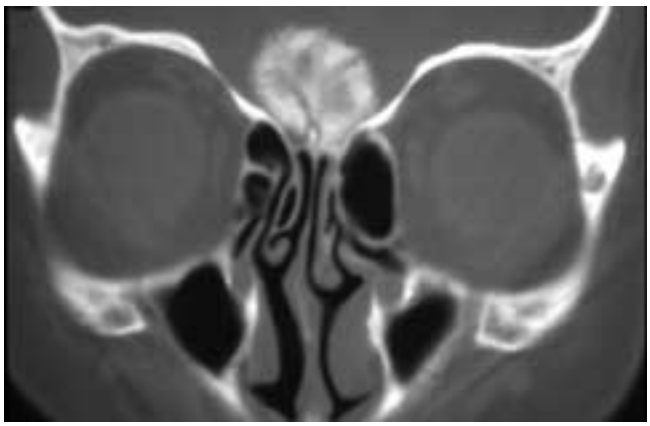

FIGURE 6-81 Coronal CT scan shows a heavily calcified ovoid mass in the anterior cranial fossa resting on the cribriform plate. This patient had an old ''burnt-out'' meningioma.

FIGURE 6-83 Sagittal T1-weighted, contrast-enhanced MR image (**A**) shows a large, enhancing mass that replaces almost the entire clivus and extends forward to fill the sinonasal cavities. There is also a large dorsal extension of this tumor. This is an unusually large chordoma with uncharacteristic exuberant ventral and dorsal growth. Sagittal T1-weighted, contrast-enhanced MR image (**B**) shows a bulky, nonhomogeneously enhancing mass in the clivus and sphenoid sinus. This is a more characteristic MR appearance of a chordoma than that shown in **A**.

of chordomas in the sinonasal tract includes chondroma, chondroblastic osteosarcoma, chondrosarcoma, and pleomorphic adenoma, all of which are fairly uncommon at this site.[120–122] Immunohistochemically, chordoma cells express cytokeratin, thus excluding tumors such as chondroma, chondroblastic osteosarcoma, and chondrosarcoma. As chordomas routinely express S-100, the differential diagnosis of a salivary tumor (namely, pleomorphic adenoma) is best excluded on light microscopy.

Chordomas have traditionally been treated by surgery plus adjuvant radiotherapy; however, recent data indicate an improved local control rate with higher-energy proton beam therapy.[123] Generally, patients with cranial chordomas have a lower metastatic rate (6.6%) than those with sacral tumors, but the former are obviously more likely to suffer morbidity/mortality due to the lack of tumor control.

On contrast-enhanced CT, the classic chordoma is a minimally enhancing, destructive lesion that has areas of dystrophic calcification and residual bone fragments. On MR imaging, chordomas are extremely variable in appearance, and they can have anywhere from low to high signal intensity on any sequence (Figs. 6-83 and 6-84).[124] Only rarely does a classic chordoma arising within the clivus grow sufficiently large to involve the posterior nasal vault and the paranasal sinuses. The only reported case in the maxillary sinus mimicked a mucocele (Fig. 6-85).[117] Recurrences of clival chordomas along the margins of the surgery have been reported to occur in the nasal soft tissues, the nasal septum, and the maxilla (Fig. 6-86)[125] (see also Chapter 12).

Choristoma

The term *choristoma* refers to histologically normal mature tissue present in an ectopic site, such as salivary tissue within the external auditory canal or thyroid tissue within the tongue base. Choristomas usually produce small incidental masses. Sinonasal or nasopharyngeal choristomas have been reported, albeit rarely.[126–128]

Nasal Glioma

A nasal glioma is also, by definition, a choristoma and not a true neoplasia, as the term *glioma* might imply. It presents

as a subcutaneous mass of the nasal bridge with intranasal extension (60%) or as a polyp confined to the nasal vault. Radiographically, an intracerebral extension or a cribriform plate defect needs to be ruled out. If an intracerebral communication, in particular a CSF communication, is found, this lesion is better classified as a cephalocele (Fig. 6-87) (see also Chapter 1). Histologically, a glioma is composed of disorganized glial and fibrous tissue.

Ectopic Pituitary

Nelson's syndrome is defined as the presence of an enlarging pituitary tumor, elevated fasting plasma ACTH, and hyperpigmentation after bilateral adrenalectomy in patients with Cushing's disease. Ectopic functioning pituitary tissue within the sphenoid sinus is a rare occurrence. The development of Nelson's syndrome presenting as a sphenoid mass was described in a young woman whose only functioning hypophyseal tissue was within the sphenoid sinus.[129]

LYMPHOPROLIFERATIVE AND HEMATOPOIETIC DISORDERS

Lymphoma

About half of all patients with malignant lymphoma clinically present with disease in the head and neck, most often as cervical lymphadenopathy. Only 10% of head and neck lymphomas are extranodal, usually involving the tonsils, sinonasal tract, and thyroid. The last usually develops in association with Hashimoto's thyroiditis.[130, 131]

Sinonasal lymphoma (SNL) is more common in Asian than in Western populations, where it represents the second most frequent group of extranodal lymphomas after gastrointestinal lymphomas. It has previously been referred to in the literature as lethal midline granuloma, malignant midline reticulosis, or polymorphic reticulosis. These are clinically inexact terms that imply a lack of definitive pathologic diagnosis. These terms have been replaced by microscopic and phenotypic classifications.[132] SNL can be classified as either B-cell, T-cell natural killer cell (T/NK-cell), or T-cell natural killer precursor cell (T/null-cell) phenotypes. The Revised European and American Lymphoma classification (REAL) is presented in Table 6-2, which includes SNL within the classification of extranodal lymphomas.

Some pertinent clinicopathologic distinctions can be made between B-cell and T-cell SNL.[133–137] B-cell phenotype SNL typically involves the paranasal sinuses, with a slight predominance in Western countries. Presenting symptoms relate to paranasal sinus involvement; patients may present late with pain, a facial or palatal mass, or ocular symptoms. These lymphomas are more likely to be associated with ocular symptoms and are more likely to have orbital extension than T/NK-cell phenotype SNL. T-cell SNL is most common in Asian and South American countries. The majority of T-cell SNLs have the natural killer T-cell phenotype T/NK-cell, however, a small percentage lack this phenotype and are classified as T/null-cell SNL. These tumors are typically located in the nasal cavity and have an aggressive, angioinvasive growth pattern that often results in necrosis and bony erosion. The term *angiocentric T-cell lymphoma* refers to those T-cell lymphomas that grow around and into vessels and are associated with necrosis. Patients with T-cell SNL are younger, with a lower male-to-female ratio than those with B-cell SNL. T-cell SNL is more commonly associated with the Epstein-Barr virus (EBV) than is B-cell SNL.[138–141] Typically, T-cell SNL, especially angiocentric

Table 6-2
REVISED EUROPEAN AND AMERICAN LYMPHOMA (REAL) CLASSIFICATION

B-Cell Neoplasms
I. Precursor B-cell neoplasm
  1. B-lymphoblastic leukemia/lymphoma
II. Peripheral B-cell neoplasms
  1. B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
  2. Lymphoplasmacytoid lymphoma/immunocytoma
  3. Mantle cell lymphoma
  4. Follicle center lymphoma, follicular
    - Provisional cytologic grades: small cell, mixed small and large cell, large cell
    - Provisional subtype: diffuse, predominantly small cell type
  5. Marginal zone B-cell lymphoma
    - Extranodal (MALT type +/– monocytoid B cells)
    - Nodal (+/– monocytoid B cells)
    - Splenic (+/– villous lymphocytes)
  6. Hairy cell leukemia
  7. Plasmacytoma/myeloma
  8. Diffuse large cell B-cell lymphoma
    - Subtype: primary mediastinal (thymic) B-cell lymphoma
  9. Burkitt's lymphoma
  10. Provisional category high-grade B-cell lymphoma, Burkitt's-like

T-Cell and Putative Natural Killer (NK) Cell Neoplasms
I. Precursor T-cell neoplasm
  1. T precursor lymphoblastic lymphoma/leukemia
II. Peripheral T-cell and NK-cell neoplasms
  1. T-cell chronic lymphocytic leukemia/prolymphocytic leukemia
  2. Large granular lymphoproliferative (LGL) disorder
    - T-cell type
    - NK-cell type
  3. Mycosis fungoides/Sézary's syndrome
  4. Peripheral T-cell lymphoma (small cell, mixed small and large cell, large cell)
    - Provisional subtype: lymphoepithelioid cell lymphoma
  5. Angioimmunoblastic T-cell lymphoma (AILD)
  6. Angiocentric lymphoma
  7. Intestinal T-cell lymphoma (+/– enteropathy associated)
  8. Adult T-cell lymphoma/leukemia (ATL/L)
  9. Anaplastic large cell lymphoma (ALCL), CD30+, T- and null-cell types

Hodgkin's Disease
1. Lymphocyte predominance
2. Nodular sclerosis
3. Mixed cellularity
4. Lymphocyte depletion
5. Provisional category: lymphocyte-rich classic Hodgkin's disease
6. Provisional category: anaplastic large cell lymphoma, Hodgkin's disease–like

Unclassifiable
1. B-cell lymphoma, unclassifiable (low grade/high grade)
2. T-cell lymphoma, unclassifiable (low grade/high grade)
3. Malignant lymphoma, unclassifiable

lymphomas, may present with, or progress to involve, numerous extranodal sites such as skin, liver, larynx, kidney, breast, testis, and prostate. In addition to the development of extranodal disease, T/NK-cell SNL may be associated with hemophagocytic syndrome, a fatal complication that may be associated etiologically with EBV reactivation.[142]

SNL is treated with a combination of local irradiation and chemotherapy with an anthracycline-based regimen. B-cell SNL is usually responsive, whereas in Asian studies, T/NK-cell SNL is less responsive and has a worse prognosis. Table 6-3 compares some recent series of B-cell and T-cell SNL patients regarding demographics and survival. Generally, survival is dependant upon tumor stage and grade rather than phenotype.

On CT and MR imaging, lymphomas in the sinonasal cavities tend to be bulky soft tissue masses that enhance to a moderate degree.[143, 144] These tumors also tend to remodel bone, although occasionally aggressive bone invasion is seen.[145–148] Most often the disease is located in the nasal fossae and maxillary sinuses.[149] Less often, lymphoma is found in the ethmoid sinuses, and only rarely is it found in the sphenoid and frontal sinuses. On MR imaging, it tends to have an intermediate intensity signal on all imaging sequences and it enhances after contrast administration (Figs. 6-88 to 6-93).

Granulocytic Sarcoma

Granulocytic sarcoma, or chloroma, is a rare complication of acute and chronic myeloid leukemia. It represents a soft-tissue infiltrate of immature myeloid elements that develops in 3% of patients with acute and chronic myeloid leukemia. The term chloroma describes the green hue seen when these tumors are sectioned. The color, caused by the cytoplasmic enzyme myeloperoxidase, fades after exposure to air. The mean patient age is 48 years, and most patients (85%) present with a solitary lesion. In the head and neck, osseous lesions have been reported in the skull, face, orbit,

and paranasal sinuses, whereas extramedullary tumors have been reported in the nasal cavity, paranasal sinuses, nasopharynx, tonsil, mouth, lacrimal gland, salivary glands, and thyroid gland.[150] An associated myeloproliferative disease is found in 48% of patients, and acute myeloid leukemia occurs in 22% of the cases. However, 30% of patients with granulocytic sarcoma have no hematologic disease at the time of initial diagnosis. The onset of granulocytic sarcoma may be a harbinger of the development of acute blast crisis within a few months of the diagnosis. The prognosis of patients with acute myeloid leukemia is not altered by the development of a chloroma; however, in patients with chronic myeloid leukemia and other myeloproliferative disorders, the granulocytic sarcoma is an ominous sign because it is associated with the acute or blastic phase of the disease.[150–152] On CT, chloromas are enhancing, homogeneous masses, usually with slightly infiltrative margins.[153] On MR imaging, they have intermediate to high signal intensities on all imaging sequences, and they enhance with contrast administration.

Multiple Myeloma

Multiple myeloma (MM) is the most common member of a group of diseases known collectively as plasma cell dyscrasias. These diseases, including Waldenstrom's macroglobulinemia, heavy chain disease, and primary amyloidosis, all have a malignant proliferation of plasma cells or lymphocytoid plasma cells with monoclonal immunoglobulin or immunoglobulin fragments in the patient's urine. The proliferation of neoplastic cells is associated with bone destruction and involves the bone marrow of the axial skeleton. However, the soft tissues can also be involved. MM usually affects patients over the age of 40 (mean age is 63) and has a roughly equal sex distribution. The most frequent complaints are bone pain (63%), weakness (23%), and weight loss (15%). Extraosseous plasmacytoma is the initial manifestation of MM in only 5% of patients.[150] In the head and neck, soft-tissue masses occur primarily in the nose, paranasal sinuses, nasopharynx, and tonsils. Patients may have oronasal

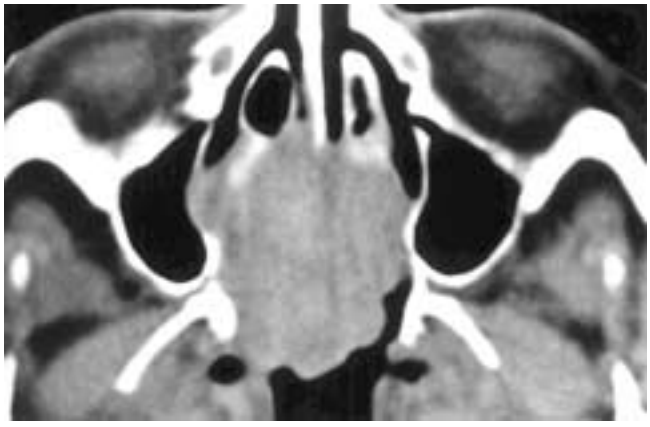
bleeding as a primary manifestation of hyperviscosity. Skeletal lytic lesions are found in 85% of patients, and a combination of lytic bone lesions, osteoporosis, and pathologic fractures is found in 63% of patients at disease onset.[148] Paraosseous tumor extension through destroyed cortical bone is found in 50% of patients at autopsy. In 10% to 12% of patients with MM, amyloidosis is present. Infection and renal failure are the primary causes of death. With the use of alkylating agents, steroids, and local irradiation, the median survival time is 20 months; 66% of patients are alive after 1 year, 32% after 3 years, and 18% after 5 years.[153] The imaging characteristics appear to be similar to those of lymphomas.

Extramedullary Plasmacytoma

Extramedullary plasmacytoma (EMP) is a rare soft-tissue malignancy composed of plasma cells. Eighty percent of these tumors occur in the head and neck, 28% occur in the nasal cavity, and 22% occur in the paranasal sinuses.[150]



VIEW IMAGE

FIGURE 6-89 Axial CT scan shows a bulky, lobulated posterior nasal fossa mass centered on the nasal septum. There is minimal thinning of the medial right antral wall. The dominant finding is expansion of the nasal vault. This patient had a large cell lymphoma.

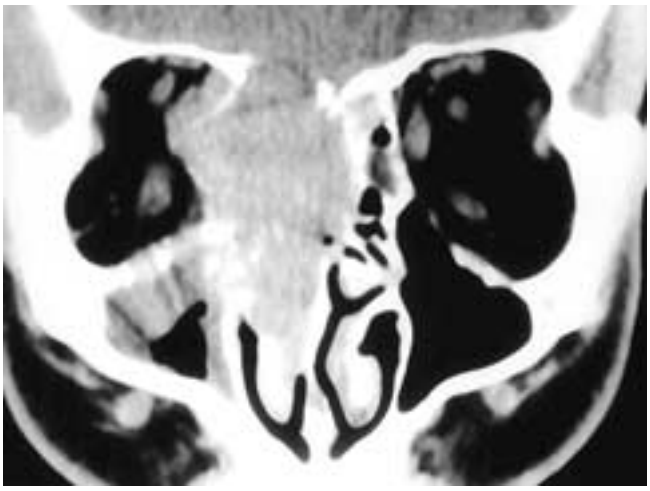


FIGURE 6-90 Coronal CT scan shows a bulky soft-tissue mass in the right ethmoid and nasal cavity. The tumor has invaded the right orbit and the floor of the anterior cranial fossa. There is also obstruction of the right antrum. This is a more aggressive appearance of a large cell lymphoma and, based on the imaging appearance, could be a carcinoma.

VIEW IMAGE

They represent 3% to 4% of all sinonasal cavity tumors.[154, 155] About 20% of head and neck EMPs are initially associated with MM. The tumors are four times more likely to occur in males than in females, and 90% of the patients are white; 95% of the tumors occur over the age of 40 years (mean is 59 years).[150] The most common presenting symptoms are a soft-tissue mass (80%), airway obstruction (35%), epistaxis (35%), local pain (20%), proptosis (15%), and nasal discharge (10%). The mean duration of symptoms is 4½ months.

Histologically, plasmacytomas range from well-differentiated cells indistinguishable from mature, benign

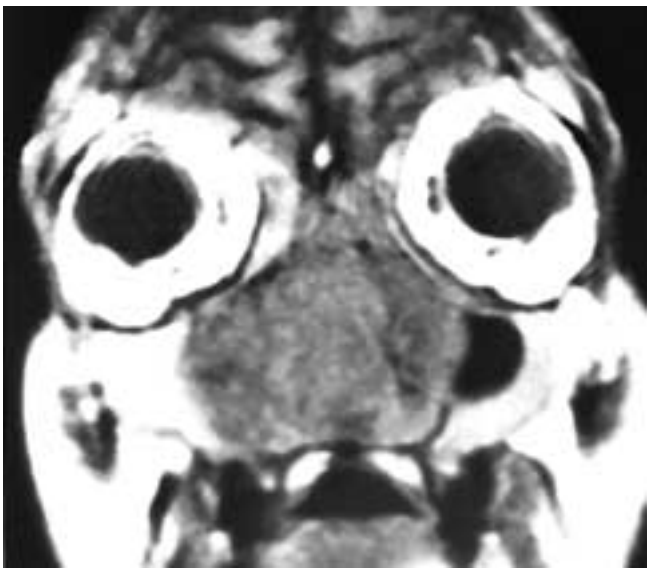

FIGURE 6-91 Coronal T1-weighted MR image shows an expansile bilateral nasal cavity mass that extends into the ethmoid and maxillary sinuses. The mass has a low to intermediate signal intensity and had a slightly higher T2-weighted signal intensity. This patient had a large cell lymphoma.

plasma cells to poorly differentiated tumor cells. The former can be distinguished from a benign plasma cell infiltrate by the demonstration of immunoglobulin clonality via immunohistochemistry. Poorly differentiated anaplastic plasmacytoma can also be distinguished from anaplastic carcinoma, ONB, melanoma, and large cell lymphoma by immunohistochemistry.[150, 156] Radiation therapy and surgery are the treatments of choice; alkylating agents and steroids help patients with painful bone lesions and patients with systemic disease. Eventually, 35% to 50% of patients with primary EMP develop MM. Local bone destruction and persistent primary tumors after radiation therapy are not necessarily poor prognostic indicators. Between 31% and 75% of patients are alive after 5 years; however, the median length of survival after the onset of MM is less than 2 years.[150]

On CT, EMPs of the sinonasal cavities are homogeneous, enhancing polypoid masses that remodel surrounding bone.[157, 158] On MR imaging they have an intermediate signal intensity on all imaging sequences, they enhance, and because they are highly vascular, they may have vascular flow voids (Figs. 6-94 to 6-97).

Langerhans' Cell Granulomatosis

Langerhans' cell granulomatosis (LCG or histiocytosis X) is the current term for a group of childhood diseases including eosinophilic granuloma (EG), Hand-Schuller-Christian (HSC) disease, and Letterer-Siwe (L-S) disease. EG is a more localized form of LCG, often manifesting as a solitary bone lesion, whereas HSC disease and L-S disease are multifocal or disseminated diseases that involve the lymph nodes, skin, liver, spleen, lung, head and neck, or gastrointestinal tract. The etiology is unknown; however, some researchers suggest that all forms of LCG are clonal.[159, 160] Others, however, believe LCG to be a benign, possibly reactive process.[161]

The head and neck are frequently involved in LCG, usually the flat bones of the skull or the jaws. Patients often present with otitis media and/or destructive temporal bone lesions. Sinonasal involvement is virtually unreported, but sphenoid involvement has been seen.[150, 163, 164]

The histology of LCG is distinctive, but immunohistochemical confirmation is important.[161, 165] LCG is characterized by a polymorphous cellular infiltrate of mononuclear

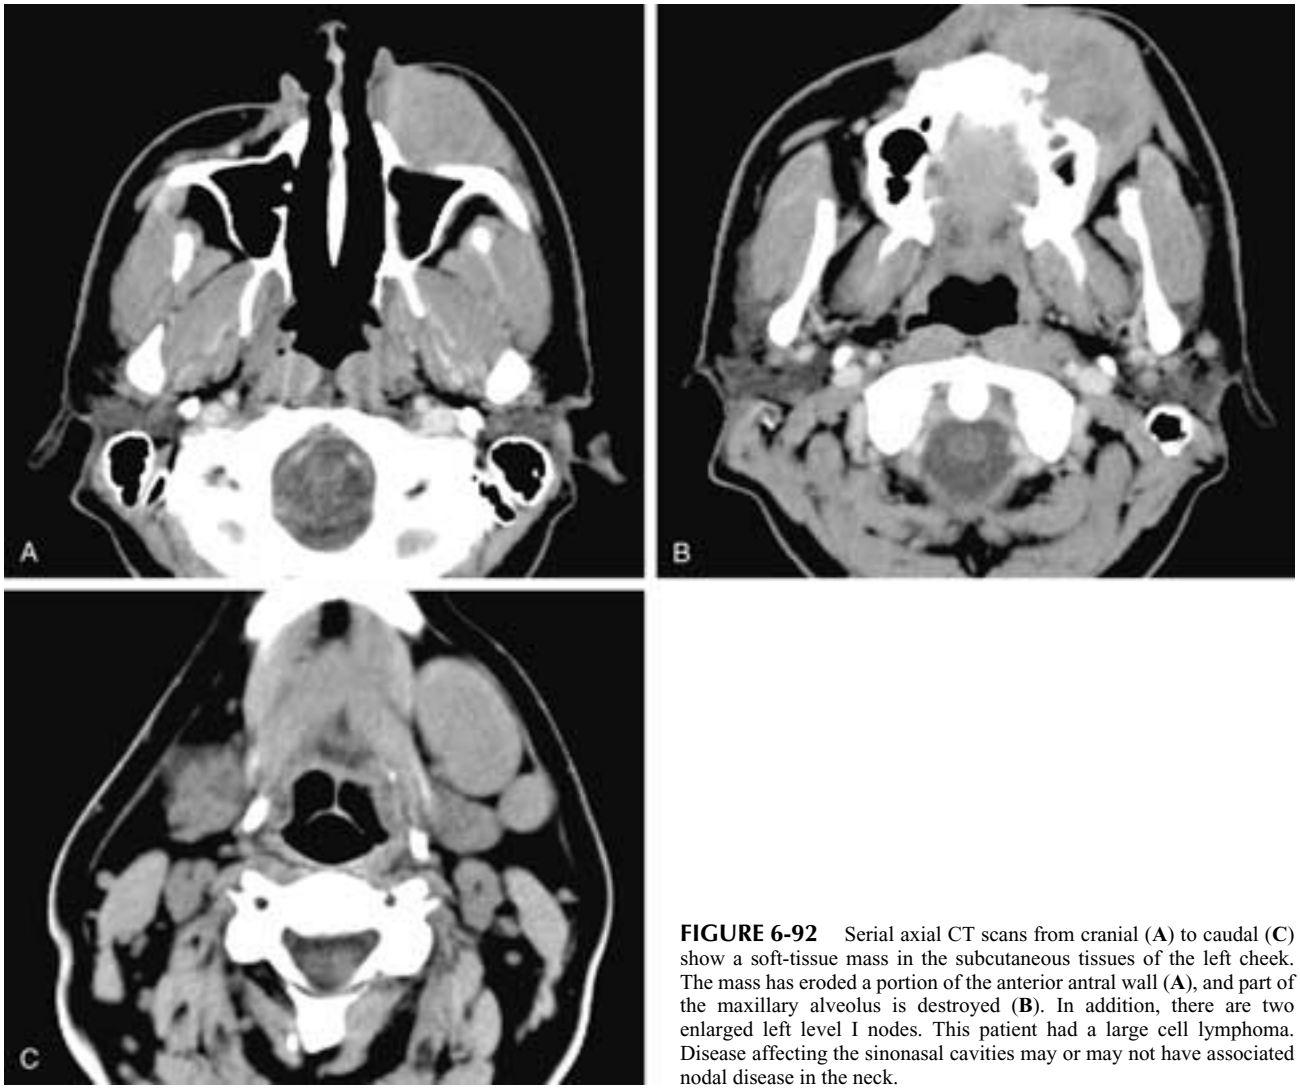

FIGURE 6-92 Serial axial CT scans from cranial (**A**) to caudal (**C**) show a soft-tissue mass in the subcutaneous tissues of the left cheek. The mass has eroded a portion of the anterior antral wall (**A**), and part of the maxillary alveolus is destroyed (**B**). In addition, there are two enlarged left level I nodes. This patient had a large cell lymphoma. Disease affecting the sinonasal cavities may or may not have associated nodal disease in the neck.

or multinucleated histiocytes (Langerhans' cells), with lobated or grooved (clefted) nuclei, mixed with varying numbers of eosinophils, granulocytes, and lymphocytes.[161, 165] Immunohistochemically, Langerhans' cells are typically positive for S-100 protein and, more specifically, CD1a. Intracytoplasmic Birbeck granules are diagnostic of LCG cells on ultrastructural analysis.[166]

The mixed infiltrate of histiocytes and eosinophils, and the presence of phagocytosis in LCG, may be mistaken for reactive histiocytosis, Hodgkin's disease, and sinus histiocytosis with massive lymphadenopathy (SHML or

Rosai Dorfman disease). The characteristic feature of SHML is prominent lymphophagocytosis (emperipolesis). SHML cells lack the typical nuclear features of LCG cells and, furthermore, lack the characteristic intracytoplasmic Birbeck granules seen on ultrastructural analysis.[166]

Treatment of LCH is based on the degree of disease involvement.[161] Biopsy or curettage of osseous lesions and, at times, low-dose radiation therapy are the treatments of choice for localized LCG. Aggressive or refractory disease may require chemotherapy. Generally, the greater the degree of organ involvement, the worse the prognosis. Alessi and colleagues subclassified 28 children with LCG as having either type I (monostotic disease—7 children), type II (multiple sites without visceral involvement—15 children), or type III (presentation with disseminated disease including visceral involvement—6 children).[162] Patients with type I disease had an excellent prognosis after local curettage, whereas patients with type III disease all died despite chemotherapy. A poor prognosis was associated with polyostotic bone disease, additional soft-tissue lesions of the skin, lymph node involvement, hepatosplenomegaly, diabetes insipidus and hypothalamic dysfunction, and disseminated bone marrow involvement.

On CT, bone involvement can vary from a well-localized destructive process to an infiltrative mass. Enhancement after contrast administration is seen on CT and MR imaging. Soft-tissue involvement is nonspecific, and again can vary

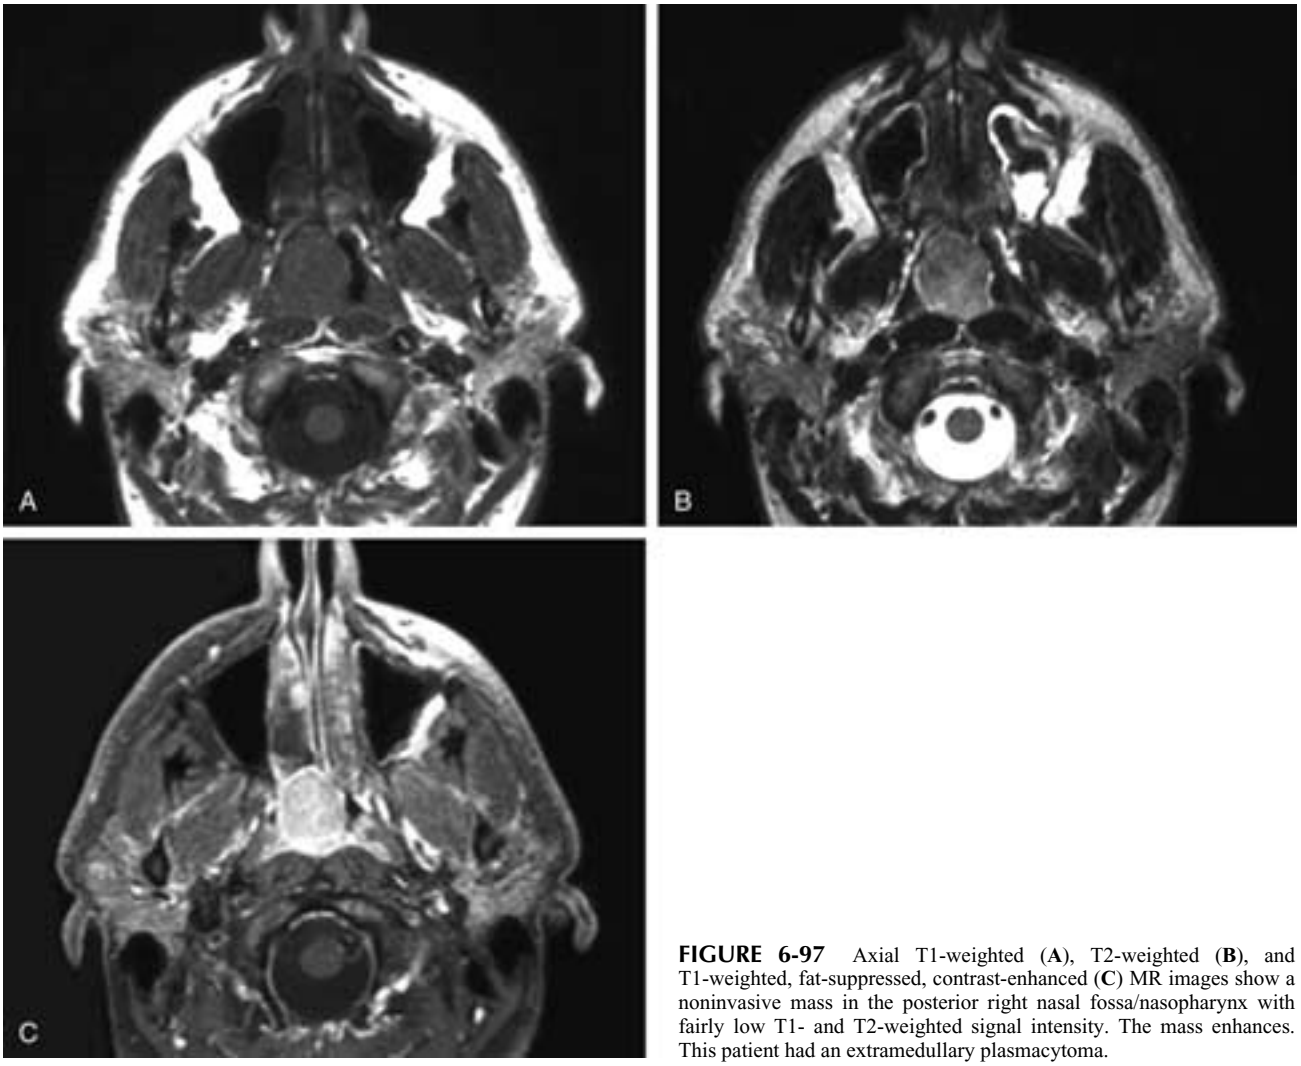

FIGURE 6-97 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images show a noninvasive mass in the posterior right nasal fossa/nasopharynx with fairly low T1- and T2-weighted signal intensity. The mass enhances. This patient had an extramedullary plasmacytoma.

from a fairly well defined mass to one that has infiltrative margins. On MR imaging, there usually is an intermediate T1-weighted signal intensity and an intermediate to high T2-weighted signal intensity.[167] As mentioned, there is marked enhancement after contrast administration. Overall, MR imaging is usually better in assessing bone marrow invasion and any soft-tissue disease, while the actual bone disease is often better seen on CT.

Rosai-Dorfman Disease

Rosai-Dorfman disease (massive lymphadenopathy with sinus histiocytosis) is a rare idiopathic benign histiocytic proliferation usually seen in young patients. The massive lymphadenopathy most commonly involves the cervical lymph nodes, with a predominant infiltration of sinusoidal histiocytes. Nearly half of the patients have extranodal involvement, the majority of which (75%) occur in sites in the head and neck. Paranasal sinus involvement has been reported, usually in conjunction with cervical adenopathy and multifocal extranodal lesions.[168–171] On CT, the paranasal sinus disease was a bulky, homogeneous mass similiar in appearance to lymphoma.

The clinical presentation depends upon the involved site. Patients may present with nasal obstruction, stridor, proptosis, decreased visual acuity, facial pain or tenderness, cranial nerve deficits, mandibular tenderness, dermal infiltrates, and mass lesions.

Rosai-Dorfman disease can be self-limiting. In other cases, surgery for locoregional lesions can result in long-term disease control. Sinonasal disease can be managed by endoscopic resection, although refractory cases may require chemotherapy, radiotherapy, steroids, or more extensive surgery. The imaging findings are nonspecific.

Thalassemia

Thalassemia is a hereditary anemia characterized by defective hemoglobin synthesis and ineffective erythropoiesis caused by reduction and abnormalities in globin chain synthesis. Disease severity correlates with homozygosity and with the ensuing relative decrease in globin production and the stability of the residual globin chain excess. Patients with thalassemia minor syndromes are heterozygous and develop mild anemia and persistent microcytosis. Thalassemia intermedia is a homozygous state characterized by a moderate hemolytic anemia that presents during physiologic stressors such as infection, pregnancy, or surgery. Thalassemia major is a homozygous state that produces severe, life-threatening anemia; it can be classified as beta-thalassemia (diminished beta-globin chains) or alpha-thalassemia (decreased alpha-chain production).

Alpha-thalassemia major usually is incompatible with life and presents as hydrops fetalis. Beta-thalassemia is an autosomal recessive disorder that occurs primarily in patients of Mediterranean origin. The defect in β-globin synthesis results in imbalanced globin chain synthesis, delayed erythroid maturation, and severely decreased red cell survival.

Patients become symptomatic early in life, requiring chronic transfusion therapy. Iron overload, due to increased gastrointestinal absorption and blood transfusion, is the major cause of tissue damage, morbidity, and death.

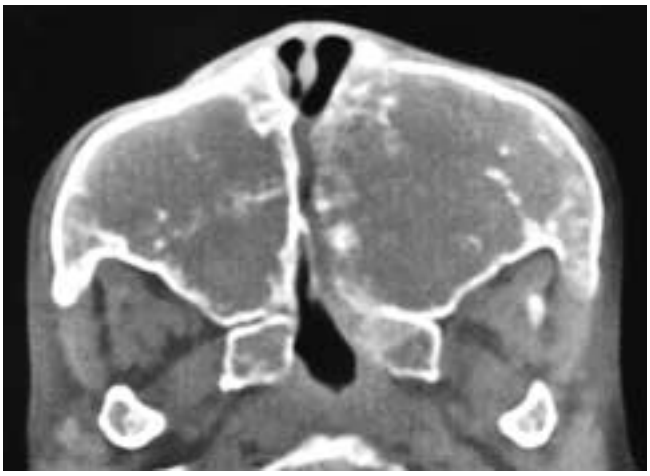

FIGURE 6-98 Axial CT scan at a wide window setting shows a markedly expanded maxilla with no development of the maxillary sinuses. The surrounding cortical bone is intact. The central portions of each maxilla are filled with expanded marrow. This patient had thalassemia.

VIEW IMAGE

The radiographic features of beta-thalassemia are due in large part to compensatory bone marrow expansion. A markedly expanded marrow space leads to various skeletal manifestations in the spine, skull, facial bones, ribs, etc. The classic radiographic changes of thalassemia in the skull include a thickened calvarium and a ''hair-on-end'' appearance. In the facial area, sinus pneumatization is delayed and the maxilla is expanded secondary to marrow expansion, which can result in both malocclusion and a cosmetic deformity. On CT, soft-tissue density material (marrow) is seen filling and expanding the maxillae, and this process may extend into the central skull base and mandible (Figs. 6-98 and 6-99).[172] Because sinus pneumatization only occurs in a bone once red marrow has converted to yellow marrow, often the frontal, sphenoid, and maxillary sinuses are poorly developed, and the only sinuses seen are the ethmoids.

Advances in the management of thalassemia major (bone marrow transplantation, iron-chelating therapy) have greatly improved the prognosis.[173, 174]

BENIGN AND MALIGNANT PRIMARY SOFT-TISSUE TUMORS

Vascular

Angiofibroma

The nasopharyngeal angiofibroma (juvenile angiofibroma) is an uncommon, highly vascular, nonencapsulated polypoid mass that is histologically benign but locally aggressive. It represents 0.05% of all head and neck neoplasms and occurs almost exclusively in males.[13] However, a few cases have been documented in females, and it has been suggested that when such a diagnosis is made, sex chromosome studies should be performed to investigate the possibility of genetic mosaicism.[175] The

Copyright © 2003, Mosby, Inc. All rights reserved.

typical patient is a male between 10 and 18 years of age, although the lesion may occasionally present in older patients.[13] The presenting symptoms include nasal obstruction, epistaxis, facial deformity, proptosis, nasal voice, sinusitis, nasal discharge, serous otitis media, headache, and anosmia. Almost all angiofibromas originate from the posterior choanal tissue near the pterygopalatine fossa and sphenopalatine foramen and fill the nasopharynx. Tumor growth is asymmetric, and one side is always the primary site of involvement. Extension into the pterygopalatine fossa occurs in 89% of the cases and results in widening of this fossa, with resultant anterior bowing of the posterior ipsilateral antral wall.[176] Although there are other slowly growing lesions that may also similarly widen the pterygopalatine fossa (e.g., lymphomas, lymphoepitheliomas, schwannomas, and fibrous histiocytomas), the vast majority of antral bowing is caused by nasopharyngeal angiofibromas.[177] The sphenoid sinus is involved by extension through the roof of the nasopharynx in 61% of cases. Angiofibromas also spread into the maxillary and ethmoid sinuses in 43% and 35% of cases, respectively.[175] Intracranial extension occurs in 5% to 20% of cases and

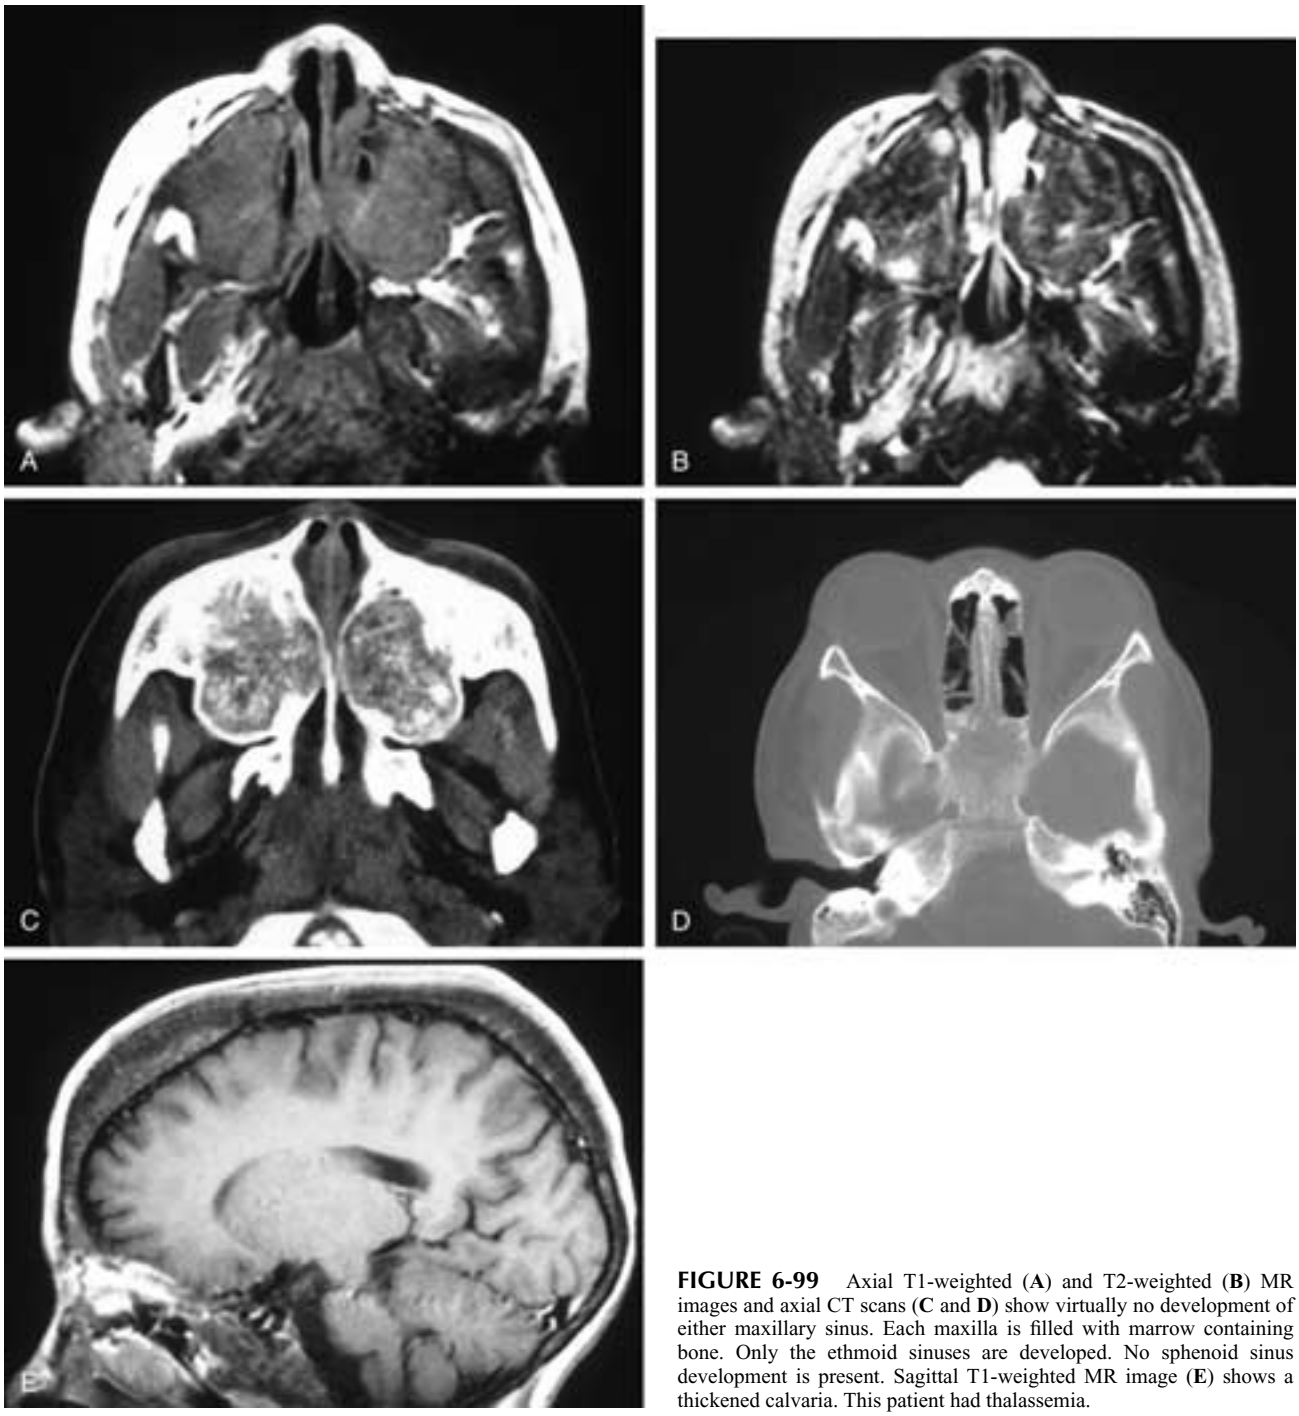

FIGURE 6-99 Axial T1-weighted (**A**) and T2-weighted (**B**) MR images and axial CT scans (**C** and **D**) show virtually no development of either maxillary sinus. Each maxilla is filled with marrow containing bone. Only the ethmoid sinuses are developed. No sphenoid sinus development is present. Sagittal T1-weighted MR image (**E**) shows a thickened calvaria. This patient had thalassemia.

VIEW IMAGE

FIGURE 6-100 Lateral view shows a large nasopharyngeal mass that has displaced the posterior antral wall anteriorly (*arrow*). The mass also extends into the sphenoid sinuses. This patient had an angiofibroma.

primarily involves the middle cranial fossa.[13] Most often this extension progresses from the pterygopalatine fossa into the orbit (through the inferior orbital fissure) and then intracranially through the superior orbital fissure. Direct intracranial extension from the sphenoid or ethmoid sinuses is uncommon. Biopsy should not be attempted in an outpatient or office facility because of tumor vascularity. Sectional imaging and angiography are sufficient to establish the diagnosis.[178] Histologically, thick-walled vessels are embedded in densely collagenized fibrous stroma. The differential diagnosis includes a fibrosed antrochoanal or nasal polyp and an angiomatous polyp.

Plain film findings of an angiofibroma include a soft-tissue nasopharyngeal mass, widening of the pterygopalatine fossa with anterior bowing of the ipsilateral posterior antral wall, and opacification of the sphenoid sinus (Fig. 6-100). A polypoid nasal mass may cloud the ipsilateral ethmoid and maxillary sinuses. If the superior orbital fissure is widened, intracranial extension will be present.

Contrast-enhanced CT shows an enhancing mass with the anatomic distribution described above (Figs. 6-101 and 6-102). Intraorbital or intracranial extension is much better visualized on CT than on plain films. On contrast-enhanced CT, the imaging must be done while contrast material is flowing freely. If scanning is delayed, the rich vascular tumor network will wash out the contrast medium. Dynamic scanning also identifies the highly vascular nature of these tumors.[179] MR imaging reveals a mass of intermediate signal intensity on T1-weighted and T2-weighted sequences, with multiple-flow voids that represent the major tumor vessels (Figs. 6-102 and 6-103). The primary imaging tasks are mapping the lesion for the surgeon and documenting any intracranial spread.[180–182] These tumors tend to deossify the adjacent skull base; however, the imaging may suggest aggressive erosion. Most often, the cavernous sinus is displaced rather than invaded, and current skull base surgical techniques usually allow such tumor extension to be resected.

Angiography demonstrates that the major feeding vessels are the internal maxillary artery and the ascending pharyngeal artery on the dominant side (Fig. 6-104). Cross-circulation from contralateral branches of the external carotid artery and occasional feeding branches from the internal carotid arteries are found. The latter are usually associated with intracranial tumor extension. Subselective angiography is usually necessary to identify all of the feeding vessels. Preoperative embolization of the external carotid artery's nutrient branches greatly reduces the blood loss at surgery.[13]

The treatment of choice is surgery. Unresectable intracranial disease, if present, can be irradiated. Control rates of 78% using a dose of 30 to 35 Gy have been reported, and an additional 15% of the cases can be controlled by a second course of radiotherapy.[183] Although the radiation affects tumor vascularity, the fibrous tumor component remains unchanged and a residual mass will be seen on imaging indefinitely. Experts disagree about the effect of estrogen therapy on angiofibromas. Although some cases of decreased tumor size and vascularity have been reported after estrogen therapy, this response is not achieved in most patients.[13] Similarly, the role of chemotherapy remains unclear.

Angiomatous Polyp

The angiomatous polyp is a fibrosed, vascularized nasal polyp, presumably the response to minor trauma.[184] A choanal polyp may become quite vascularized and is termed an *angiomatous polyp.* The significance of this lesion is that

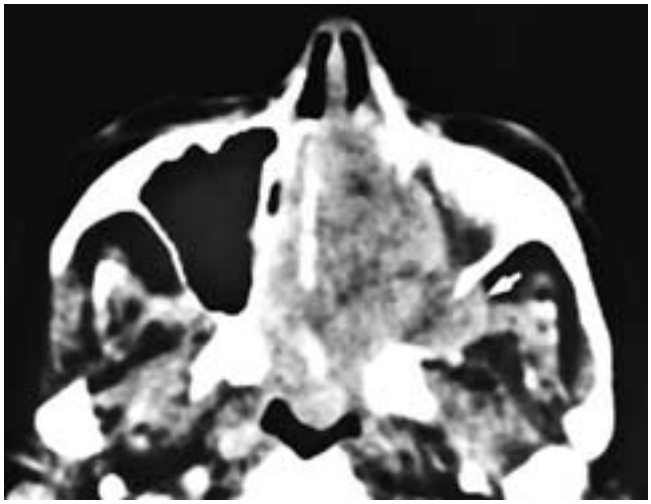

FIGURE 6-101 Axial contrast-enhanced CT scan shows a left nasopharyngeal and nasal fossa enhancing mass that has extended into the left antrum, widened the left pterygopalatine fossa, and extended into the left infratemporal fossa (*arrow*). There were only obstructed secretions in the right nasal fossa. This patient had an angiofibroma.

VIEW IMAGE

FIGURE 6-102 Axial **(A)** and coronal **(B)** CT scans show a large enhancing mass that fills the nasopharynx and nasal fossae, bows the posterior wall of the right maxillary sinus forward, and extends into the right infratemporal fossa. The tumor has also destroyed the floor of the sphenoid sinus and the right middle cranial fossa. There is a nonenhancing region in the vicinity of the left sphenoid sinus. Axial T2-weighted **(C)** and coronal **(D)** proton density MR images show that the mass is filled with serpiginous signal voids, reflecting its highly vascular nature. The left sphenoid sinus is filled with high T2-weighted fluid. This patient had a large angiofibroma with a left sphenoid sinus mucocele. The skull base was not destroyed, but only deossified from the chronic pressure of the tumor. Both cavernous sinuses were intact but were elevated by the mass.

histologically it can be confused with a nasopharyngeal angiofibroma.[176] Several points differentiate these two lesions: (1) the angiomatous polyp is located primarily in the nasal fossa and not in the nasopharynx; (2) the polyp does not extend into the pterygopalatine fossa and only rarely protrudes into the sphenoid sinuses. In these cases, the tumor enters the sinus through the anterior wall and not the sinus floor, as with angiofibromas; (3) these polyps do not extend intracranially; (4) on angiography the polyps have only a few demonstrable feeding vessels compared with the rich vascular supply of the angiofibroma; (5) on CT the angiomatous polyp does not enhance as well as the angiofibroma; (6) vascular flow voids are usually not seen on MR imaging, as they are in angiofibroma; (7) these polyps are easily ''shelled out'' surgically, as are routine nasal polyps, whereas the nasopharyngeal angiofibroma is difficult to remove from its primary attachment site; and (8) angiography and embolization are not necessary in patients with angiomatous polyps (Fig. 6-105).

The pathologic distinction between an angiomatous polyp and an angiofibroma may be difficult, and hence the pathologist may need to rely on the radiologist's impression in arriving at a correct diagnosis.

Hemangioma

Hemangiomas of the nasal cavity occur most commonly on the septum (65%), lateral wall (18%), and vestibule (16%). Most arise in the anterior septum near Kisselbach's plexus, and most are of the capillary type. Lesions arising on the lateral wall usually are of the cavernous type. Epistaxis and nasal obstruction are the most common patient complaints. Simple excision is generally curative for these lesions, which rarely exceed 2 cm in their greatest dimension. In the nasal cavity, hemangiomas also tend to develop in the inferior and middle turbinates. These lesions are diagnosed when small because they cause dramatically severe epistaxis. Rarely, intranasal hemangiomas may develop in the second trimester of pregnancy. Most of these lesions spontaneously regress within 4 to 8 weeks after delivery.[185] Hemangiomas of the paranasal sinuses are very rare; two have been described in the maxillary sinuses and two in the sphenoid

Copyright © 2003, Mosby, Inc. All rights reserved.

sinuses. The sphenoid sinus cases showed destruction of the skull base.[185]

On CT, these hemangiomas enhance, and in the nasal cavity they are usually inseparable from the middle or inferior turbinates. Hemangiomas have an intermediate signal intensity on all MR imaging sequences they enhance, and vascular flow voids occasionally may be present (Figs. 6-106 to 6-108).

Hemangiomas can also occur as solitary lesions in bone. These tumors account for only 0.7% of all primary bone tumors. In the head and neck, the most common sites are the skull (53%), mandible (10.7%), nasal bones (9%), and cervical vertebrae (6%). Although many patients have a history of local trauma, a causal relationship remains doubtful. The lesions occur twice as often in females as in males; the average age of onset is 31 years. Most commonly, patients experience a firm, nonpainful swelling that is associated with a pulsating sensation. Actual bruits are rarely heard. When hemangiomas involve the facial bones and mandible, angiograms have revealed that the blood supply is from the facial artery or the internal maxillary artery. The inadvertent surgical violation of an intraosseous hemangioma can be associated with exceptionally rapid blood loss, often as much as 3500 ml. Even so, surgery is the primary treatment of choice. Embolization may greatly reduce operative blood loss, provided that the operation is performed shortly after embolization, before a collateral circulation can develop.[116]

Radiographically these lesions have a ''sun ray,'' ''soap bubble,'' or ''honeycomb'' appearance and enhance on contrast-enhanced CT scans. On MR imaging, they have low to intermediate T1-weighted and high T2-weighted signal intensity. They also enhance (Fig. 6-109).

Angiosarcoma

Angiosarcoma refers to malignant neoplasia derived from vascular tissue. The term includes other vascular tumors, such as hemangioendothelioma, in which endothelial differentiation is more prominent, or lymphangiosarcoma, derived from lymphatic tissue. Angiosarcomas account for only 2% to 3% of all soft-tissue sarcomas. Approximately half of all angiosarcomas occur in the skin and subcutaneous tissues of the head and neck, particularly the scalp, legs, and trunk. A smaller percentage of angiosarcomas occur in the breast (particularly after radiotherapy for breast carcinoma), liver (particularly after Thorotrast exposure), bone, and spleen.[186, 187]

Cutaneous angiosarcomas occur over a wide age range but are most common in the seventh decade of life. There is a male predominance. Cutaneous and osseous angiosarcomas may present as raised or flat, spreading blue or red masses that can have a bruise-like appearance, causing dull local pain and swelling of the affected region.

Sinonasal and nasopharyngeal angiosarcomas are extremely uncommon, comprising 11% of head and neck angiosarcomas.[187–189] They present with epistaxis, nasal obstruction, headaches, and proptosis.[190] Angiosarcomas can also occur as primary intraosseous tumors and represent less than 1% of all primary bone malignancies. Head and neck angiosarcomas comprise 15% of solitary osseous angiosarcomas, arising most frequently in the mandible and skull.

FIGURE 6-105 Axial CT scan (**A**) shows a right nasal fossa polypoid mass that extends back into the nasopharynx but does not arise there. The mass does not extend into the pterygopalatine fossa or the sphenoid sinus. A biopsy specimen was interpreted as an angiofibroma. **B**, A lateral subtraction angiogram shows only focal areas of increased vascularity, without the typical vascular appearance of an angiofibroma. This patient had an angiomatous polyp.

The histologic appearance of angiosarcoma varies dramatically with the tumor grade. Well-differentiated angiosarcoma (malignant hemangioendothelioma, hemangiosarcoma) produces obvious blood-filled vascular spaces. There is a combination of ''closed'' lumina, which are finite and delineated, as well as serpiginous ''open'' lumina, which are insidiously infiltrating interanastomosing spaces. Low-grade angiosarcomas produce abundant open vascular lumina, and have a minimal solid component and a low-grade cytology. High-grade angiosarcomas are densely cellular, infiltrative sarcomas. The amount of malignant vascular lumen formation varies and may be focal. Cytologically, these tumors are frankly malignant, with nuclear pleomorphism and atypical mitotic figures. Immunohistochemistry may be necessary to distinguish high-grade tumors from other sarcomas, namely the demonstration of Ulex, CD31 and CD34 expression.

Surgical resection is indicated as the primary treatment for angiosarcomas. However, the insidious infiltrating pattern of angiosarcoma may render complete resection impossible; therefore, adjuvant radiotherapy may be necessary. Local recurrences are common. The rate of cervical lymph node metastasis reported for cutaneous angiosarcomas varies from 10% to 41%, and the reported

rate of distant metastasis ranges from 33% to 63%.[191] The 5-year survival rate is poor, ranging from 41% to 18%.

The prognosis for intraosseous angiosarcomas varies with the tumor grade. Grade I lesions recur locally but do not metastasize, as do grade II and III lesions. For patients with solitary tumors, there is a 20% 5-year survival rate. The 5-year survival rate for patients with multifocal osseous tumors is 36%, reflecting the predominance of grade I tumors in this group. Inexplicably, sinonasal tumors appear to have a better prognosis than skin, soft-tissue, and osseous tumors, with a lower recurrence rate, a higher salvage rate, and a lower metastatic rate. Barnes reported that 6 of 10 patients with sinonasal angiosarcomas were recurrence free after 0.5 to 5 years (median, 29 months), and an additional patient was disease free at 12 years after one recurrence at 8 years.[188–191] On CT and MR imaging these tumors are aggressive, bone-destroying lesions with considerable enhancement.

Hemangiopericytoma

Hemangiopericytomas (HPCs) are uncommon vascular lesions that arise primarily in the lower extremities, retroperitoneum, and pelvis. However, 15% occur in the head and neck, and of these, 55% arise in the nasal cavity.[193] HPCs are thought to be derived from Zimmerman's pericytes, contractive cells that surround the outer aspect of small vessels. The lower extremities and the retroperitoneum-pelvis are the most common sites for HPCs. The head and neck is the third most common site; tumors occur in the neck, the perioral soft tissues, and, lastly, the sinonasal tract. Sinonasal hemangiopericytomas (SNHPCs) present as gray to tan, spongy, vascular, polypoid masses. Nasal obstruction and epistaxis are common presenting symptoms.[194, 195] Other presenting complaints include watery rhinorrhea, serous otitis media, proptosis, infraorbital anesthesia, and facial pain. SNHPCs generally involve the nasal cavity along with one or more sinuses. A review of the literature revealed an overall recurrence rate of 19% (22 of 115 cases). The majority of recurrences (19 of 22) were single (16%), and most (14 of 19) occurred within the first 5 years after resection. However, first recurrences after the first 10 years have occurred. Multiple recurrences were a rarer finding, seen in only 4 of 115 cases. Overall, three patients (2.6%) developed metastases (usually locoregional sites and local lymph nodes). Four patients (3.5%) ultimately died of disease (usually from a lack of local control). This confirms the general low-grade malignant potential of this neoplasm. It appears that no single feature of SNHPC can predict the course of this basically low-grade neoplasm. The prognosis of SNHPC most likely strongly depends on the tumor stage at initial presentation and on the completeness of primary resection. Features such as mitotic rate, necrosis, and nuclear pleomorphism are probably significant for high-stage or incompletely resected tumors.[196] The diagnosis of SNHPC remains one of histologic pattern recognition, and traditionally, immunohistochemistry has aided in excluding other diagnoses. Vimentin has been consistently expressed by the tumor spindle cells of HPC. However, recent studies have shown that factor XIIIa is also expressed by HPC (as well as by tumors of fibrohistiocytic

differentiation) and hence may be yet another helpful positive marker in establishing an immunohistochemical profile. The role of chemotherapy is still evolving, but initial reports show promise.[185, 194, 197]

Microscopically, fusiform or spindle cells can be seen, forming short fascicles and bundles that become more dense around vessels. The abundant vessels have typical cuffs of perivascular hyalinization. Staghorn vessels may be rare. Nuclear pleomorphism is not normally present in SNHPCs.

On CT, HPCs are expansile, bone-remodeling lesions with a variably enhancing, fairly homogeneous appearance (Figs. 6-110 to 6-112). On MR imaging, they enhance and have low to intermediate T1-weighted and higher T2-weighted signal intensity. They tend to occur in the nasal fossa and in the maxillary sinus.[198]

Kaposi's Sarcoma

The classic form of Kaposi's sarcoma (KS) is an indolent tumor that occurs most commonly as soft red nodules on the lower limbs and, less commonly, on the upper limbs. Lesions may be multicentric and coalescent, but they rarely exceed 2 cm. Patients with classic KS are usually over the age of 50 at the time of tumor diagnosis, although 3% to 4% of the cases of the classic form are diagnosed in patients less than 15 years old. Patients with classic KS usually have long survival periods and die of something other than KS.

From the literature and the files of the Armed Forces Institute of Pathology (AFIP), Gnepp, Chandler, and Hyams compiled a total of 83 cases of classic KS, which affected the head and neck.[199] Of all the classic KS cases, 8% affected cutaneous sites on the head and neck, and only 2% affected the mucosal surfaces. Mucosal sites included the conjunctiva, palate, tongue, gingiva, and tonsil. Dermal sites included the eyelids, nose, ears, and face. By comparison, HIV-associated KS very commonly affects the skin of the head and neck (32%) and upper airway mucosal surfaces (19%). Common sites include the palate, gingiva, buccal mucosa, tongue, larynx, trachea, nasal cavity, and paranasal sinuses. These patients tend to be decades younger than patients with the classic cases (mean age, 38 years), though there is overlap among the two age groups.[199–204] The imaging findings are not diagnostic and usually show a noninfiltrating soft-tissue mass.

Muscle

Malignant soft-tissue sarcomas (STSs) represent approximately 1% of all newly diagnosed malignancies in the United States.[205] The 1991 NCI (National Cancer Institute) SEER (Surveillance, Epidemiology, and End Results) data report that the U.S. incidence of reported new sarcomas for that year represented 5700 cases.[206] The majority of primary STSs originate within the extremities (59%), followed by the trunk (19%), retroperitoneum (13%), and head and neck (9%).[207] Sarcomas occur over a wide age range, starting in the first decade of life; however, the peak incidence occurs after the sixth decade of life.[208]

Leiomyoma and Leiomyosarcoma

Sinonasal smooth-muscle neoplasia are derived from the perivascular smooth-muscle tissue that is abundant in the

Copyright © 2003, Mosby, Inc. All rights reserved.

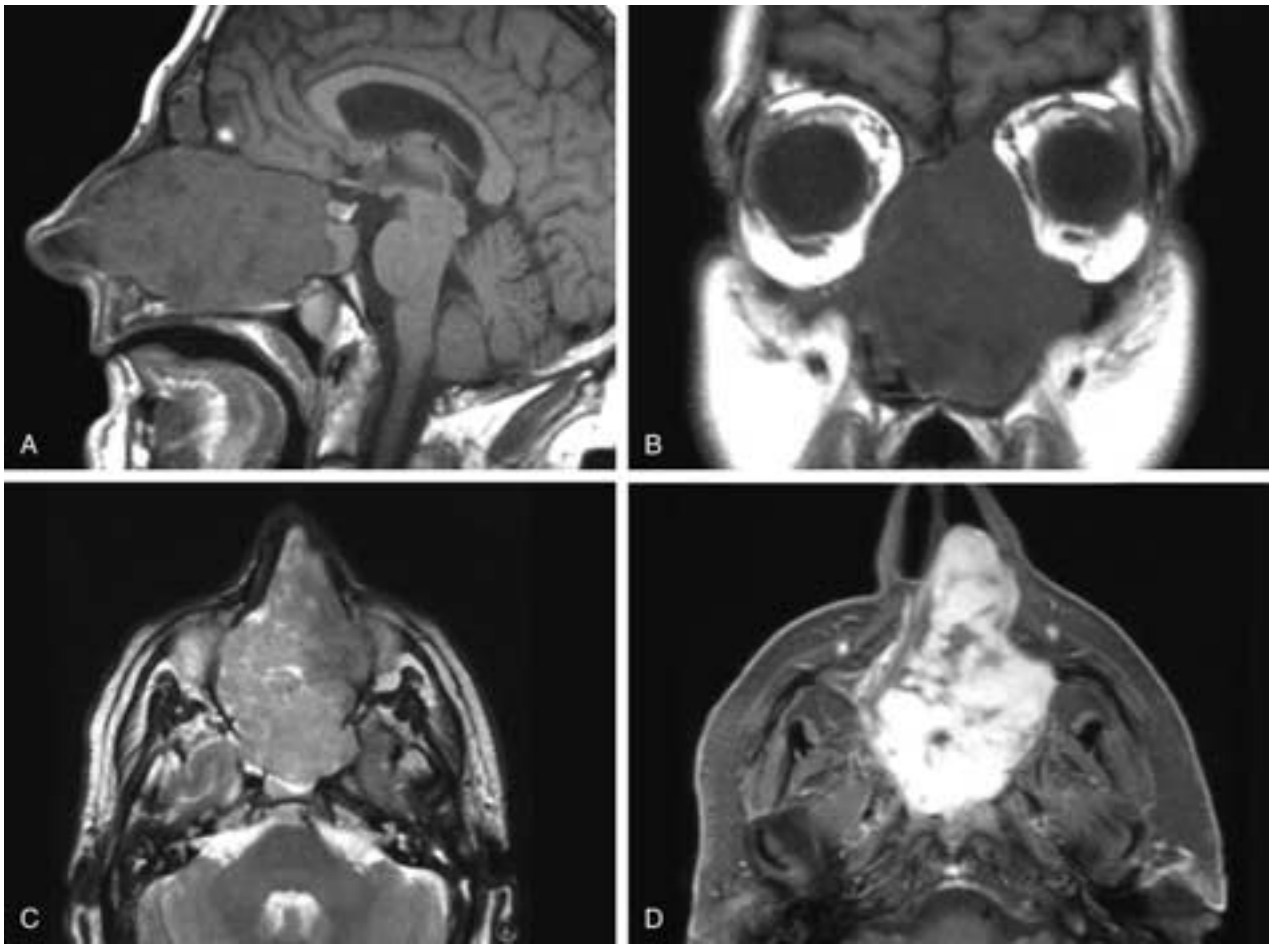
sinonasal tract. Both leiomyomas and leiomyosarcomas are rare occurrences. Fu and Perzin identified only two leiomyomas and six leiomyosarcomas from 256 nonepithelial sinonasal tumors.[209]

Leiomyomas have been reported to arise from the nasal septum, turbinates, vestibule, and choanae.[210–213] As the vascular component may be prominent, leiomyomas may present with epistaxis. Sinonasal leiomyosarcomas are rare, with fewer than 50 reports in the literature.[214, 215] On occasion, leiomyomas may present as more extensive lesions involving multiple sinuses.[216] The AFIP reported on nine cases of sinonasal tract leiomyosarcoma, which constitute the largest such series.[217] Either the nasal cavity alone or contiguous paranasal sinuses were involved. There is an equal sex distribution and an average age incidence of 50 years.[218] The sinonasal symptoms are nonspecific; patients complain of unilateral nasal obstruction, bleeding, and pain.

Leiomyomas are benign smooth-muscle tumors, the vast majority of which affect the female genital tract. In a compiled series of 257 head and neck leiomyomas, the most common sites of occurrence were the cervical esophagus (36%), subcutis (23%), and oral cavity (20%). The nasal cavity and sinuses were affected in only eight (3%) cases; the turbinate was a site of preference.[219] Five of these eight cases could be subclassified as angioleiomyomas; in all likelihood they were derived from the nasal erectile vasculature, which has thick vascular walls. Angioleiomyomas have been associated clinically with sharp knife-like pain, which probably relates to vascular constriction.

Histologically, leiomyomas are composed of bland whorls of spindled cells with blunt cigar-shaped nuclei. Immunohistochemistry confirms the expression of smooth muscle markers (actin, desmin). Angioleiomyomas have a prominent vascular component that may be compressed or thick-walled. The absence of nuclear pleomorphism, necrosis, and a prominent mitotic rate separates leiomyomas from leiomyosarcomas. Leiomyosarcomas are distinguished from leiomyomas by the presence of more than 10 mitoses per high-power field, atypia, and necrosis. The malignant cells of the epithelioid variant appear less spindled and more cuboidal. This variant is more likely to arise in the stomach or the mesentery but has been found in head and neck sites.[217]

On imaging, these tumors, like most sarcomas, tend to be homogeneous masses, often primarily expansile rather than invasively destructive (Fig. 6-113). They tend to have high



VIEW IMAGE

FIGURE 6-113 Sagittal (**A**) and coronal (**B**) T1-weighted MR images and axial T2-weighted (**C**) and T1-weighted, fat-suppressed, contrast-enhanced (**D**) MR images. In **A** and **B**, there is a fairly homogeneous, expansile nasal fossa mass that has elevated the floor of the anterior cranial fossa and bowed the lamina papyracea laterally. The medial floor of the left orbit is also elevated. There was no gross intracranial invasion or invasion of either orbit. The mass is nonhomogeneous on the T2-weighted and contrast-enhanced images. This patient had a leiomyosarcoma.

Copyright © 2003, Mosby, Inc. All rights reserved.

T2-weighted signal intensity, and they enhance after contrast administration.

Both leiomyomas and leiomyosarcomas are treated primarily by surgery. Resection can be conservative for leiomyomas, as these are curable. Sinonasal leiomyosarcomas require a wider surgical approach, as they are locally aggressive tumors. About 75% of patients have a local recurrence and 35% develop metastases. At least 50% of patients die of the disease, usually within 2 years of diagnosis.[218] Adjuvant radiotherapy or chemotherapy has no proven efficacy.[217] Tumor stage and distribution have been found to affect disease-free survival. Kuruvilla and colleagues found that of 30 patients with sinonasal leiomyosarcomata, 10 had tumors confined to the nasal cavity, none of which recurred.

Rhabdomyoma

Rhabdomyomas are rare benign tumors with skeletal muscle differentiation. They represent about 2% of all skeletal muscle tumors.[219] Clinically, rhabdomyomas can be classified as either cardiac or extracardiac.

Cardiac rhabdomyomas are most commonly associated with tuberosclerosis. Extracardiac rhabdomyomas are rare but have a tendency to affect head and neck sites such as soft tissues of the face and neck, the oral cavity, and the larynx. Histologically, rhabdomyomas can be classified as either fetal type (myxoid versus cellular types), adult type, or juvenile-intermediate type; histologically, the last type lies between the fetal and adult types. In a compiled series of 46 head and neck fetal rhabdomyomas, about half of the patients were in their second decade of life or older at diagnosis, and there was a male predisposition.[219] Five of these cases (11%) originated in the nasopharynx.[220, 221]

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is a soft-tissue sarcoma of skeletal muscle derivation. It comprises 20% of all soft-tissue sarcomas, and it is the most common soft-tissue sarcoma in children (75%). It is the seventh most common pediatric malignancy following leukemia, CNS tumors, lymphoma, neuroblastoma, Wilms' tumor, and osteogenic sarcoma.[221] The majority of patients with RMS (78%) are under 12 years of age, and 43% of patients are under 5 years of age. Only 7% of cases occur in the second decade of life, and 2% to 4% of cases occur in each subsequent decade. In the head and neck, the most common sites for all RMSs are the orbit (36%), nasopharynx (15.4%), middle ear and mastoid (13.8%), sinonasal cavities (8.1%), face (4.5%), neck (4.1%), larynx (4.1%), and oral cavity. Sinonasal RMS may occur over a wide age range and commonly presents with nasal obstruction.[223–226]

Histologically, RMS can be classified as embryonal, botryoid (a variant of embryonal RMS), alveolar, and pleomorphic types based on the growth pattern, differentiation, and shape of tumor cells. The majority of head and neck RMSs can be classified as either the embryonal type or its botryoid variant, or alveolar. Embryonal RMS (ERMS) is composed of round cells with darkly staining hyperchromatic nuclei, scant cytoplasm, short, spindled cells with central elongated nuclei, tapered ends, and eosinophilic or amphophilic cytoplasm. Botryoid ERMS (5% of cases) is a noteworthy subtype that has a characteristic polypoid ''bunch of grapes'' clinical appearance. It is associated with the most favorable prognosis of all RMSs. Histologically, it grows as a polypoid tumor with a prominent myxoid stroma in which hypocellular and more cellular areas are seen with a subepithelial condensation of tumor cells, the *cambium layer*. Most RMSs arise from skeletal or cardiac muscle cells.

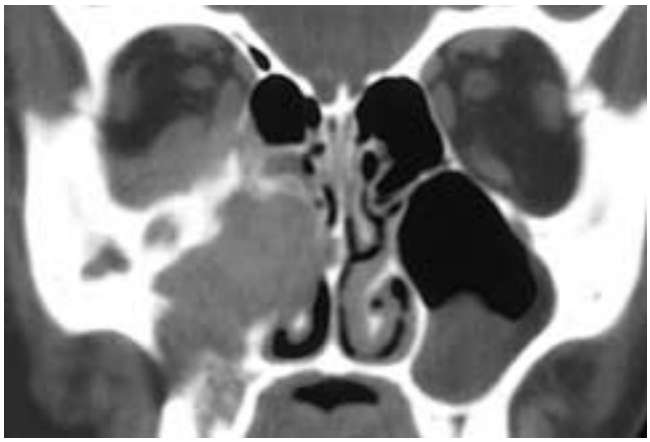


FIGURE 6-114 Coronal CT scan shows a soft-tissue mass in the right maxillary sinus. The medial sinus wall and portions of the antral roof are destroyed, and the tumor extends into the right orbit, ethmoid sinuses, and right nasal cavity. Despite these local areas of destruction, there are large areas where there is intact bone adjacent to the tumor. This patient had a rhabdomyosarcoma.

VIEW IMAGE

The general approach to RMS is resection plus adjuvant therapy. Regional lymph node sampling is appropriate; however, prophylactic lymph node dissection is not necessary. Resection followed by chemotherapy is the mainstay of therapy. Radiation therapy is not necessary after complete surgical resection with adequate margins.[227] Survival depends on the site (orbit better than parameningeal), histologic type (botryoid and embryonal better than alveolar), and stage. Tumors at nonorbital and nonparameningeal sites also have a favorable prognosis.

On imaging, RMSs usually have elements of both bone remodeling and bone destruction. On contrast-enhanced CT, these tumors enhance moderately and generally homogeneously. On MR imaging, they also tend to be remarkably homogeneous, they have intermediate signal intensities on all imaging sequences, and they enhance with contrast (Figs. 6-114 to 6-116). They can also appear on imaging as indistinguishable from SCC.

Lipoblastic

Lipoma and Lipoma-Like Lesions

These lesions, which include the ordinary lipoma, myxoid lipoma, angiolipoma, pleomorphic lipoma, spindle-cell lipoma, myelolipoma, hibernoma, and lipoblastoma, have various reported frequencies; however, they have not been reported to arise within the sinonasal cavities. The lipomas are discussed in Chapter 41.

Liposarcoma

Liposarcoma is one of the most common soft-tissue sarcomas of adulthood, usually occurring in the lower extremities and retroperitoneum. The head and neck region

FIGURE 6-115 Axial T1-weighted MR image shows a homogeneous mass in the left infratemporal fossa extending into the left antrum and the skull base. The mass has an intermediate signal intensity. This patient had a rhabdomyosarcoma.

is involved in (5.6%) of liposarcomas.[186] The soft tissues of the neck, scalp, and face are the most common sites for liposarcomas above the clavicles, comprising 54% of head and neck cases.[228] Hypopharyngeal and laryngeal sites were affected in 38% of 76 cases of head and neck liposarcoma reviewed from the Royal Marsden Hospital over a 50-year period.[228] The sinonasal tract is an extremely rare site for either liposarcoma or lipoma.[185]

Liposarcomas can be polypoid pedunculated tumors that are soft and yellow/tan/gray upon sectioning. A spectrum of histology is seen, ranging from low-grade (lipoblastic liposarcoma, lipoma-like, sclerosing liposarcoma, or atypical lipoma) or intermediate to high-grade (myxoid liposarcoma, pleomorphic liposarcoma, round cell liposarcoma, dedifferentiated liposarcoma). Low-grade tumors are characterized by an abundance of mature, histologically benign adipose tissue coursed by collagenous fibrous tissue. Lipoblasts may be focal. They have characteristic ''chicken claw''–shaped nuclei that are indented by cytoplasmic fat globules. Their chromatin is usually dense and pyknotic, but enlarged nucleoli may be found. Myxoid liposarcoma is a common histologic pattern generally seen in soft-tissue liposarcoma. The stromal background is loose and myxoid, perforated by a fine ''chicken-wire'' meshwork of arborizing vessels. The lipoblasts appear as univacuolated signet ring cells and multivacuolated cells.

Generally, liposarcomas are properly treated by resection with adequate margins. Radical neck dissection is not usually warranted for low-grade tumors, but high-grade liposarcomas may develop locoregional metastases. The rarity of this tumor in the sinonasal tract precludes discussion of specific disease-free survival.

Based on the general experience with liposarcomas elsewhere in the body, on CT these lesions have an overall low (fatty) attenuation value (-65 to -110 HU), and irregular areas of soft-tissue density are seen within the lesion. The tumor margins may infiltrate adjacent soft tissues. MR imaging shows a nonhomogeneously high T1-weighted and an intermediate T2-weighted signal intensity.[229]

Fibroblastic

Fibrosarcoma (Including Desmoid Tumor)

Fibrosarcomas (desmoid tumors, aggressive fibromatoses) are infiltrative, nonmetastasizing, unencapsulated fibroblastic tumors that account for 12% to 19% of all soft-tissue sarcomas (STSs). They occur most often in the lower extremities and trunk; only 15% occur in the head and neck. Most head and neck tumors involve the sinonasal cavities (18.3%), larynx (14.8%), and neck (sternocleidomastoid) (6.1%). Fibromatoses (desmoid tumors, grade I fibrosarcomas) are more likely to occur in the pediatric population. Higher-grade fibrosarcomas (grades II/III) usually arise in patients between 20 and 60 years of age,[185] but may also occasionally occur in the pediatric population.[209, 230]

Grade II or III head and neck fibrosarcomas are more likely to present as bony jaw tumors than as STSs. Those occurring in the older population (30%) are usually the secondary jaw sarcomas, arising in previously irradiated or diseased bone such as bone with fibrous dysplasia, Paget's disease, giant cell tumors, bone infarcts, and osteomyelitis.

Fibromatoses (desmoid tumors) are histologically very bland and well differentiated, and appear as densely cellular spindle cell malignancies producing a collagenous matrix. The fascicles or bundles of tapered spindle cells grow in a variable intersecting pattern, seen on cross-section as ''herringbone'' areas. The diagnosis is firmly established on biopsy when the pathologist can identify the bland fibroblasts insidiously infiltrating host tissue. Examination during surgery shows that this white-tan scar-like tumor sends out innumerable tentacles, making complete extirpation virtually impossible. Positive resection margins are the rule. Nuclear pleomorphism, a significant mitotic rate, and necrosis are generally not seen, and, when present, indicate transformation to a higher grade (grade II or III fibrosarcoma).

Complete surgical excision with ample margins is the treatment of choice. Recurrences after resection are common, and in some series recurrence rates are as high as 90%.[208, 231] Progression to higher-grade fibrosarcoma may occur in occasional cases, usually after radiotherapy. Grade II and grade III fibrosarcomas develop local recurrences within 18 months of treatment and metastases within 2 years of recurrences.[185] The overall prognosis depends on the adequacy of the surgical resection, sarcoma grade, size, and location, male sex, and the presence of pain or cranial nerve symptoms. Of these parameters, sarcoma grade and resection margin status are probably the most important. Only 1% to 11% of patients develop positive regional lymph nodes; however, the 5-year survival rates are only 33% to 69%.[185]

Bony fibrosarcomas tend to spread more aggressively than their soft-tissue counterparts. Most grade II or grade III jaw fibrosarcomas have 5-year survival rates ranging from 27% to 40%. Metastases occur to the lungs and to other bones; only 3% spread to regional lymph nodes.[232] In addition, the younger the patient is when the tumor appears, the better is the prognosis. Although the local recurrence rate of pediatric fibrosarcoma is similar to that for adults (17% to

47%), younger patients have metastases in only up to 14% of cases, and they have a higher 5-year survival rate of 85%.[185] In a series of sinonasal fibromatoses, five patients (21%) (four adults and one child) developed single or multiple recurrences within 6 to 34 months.[155, 233]

The imaging findings are nonspecific. On CT, fibrosarcomas have a generally homogeneous, minimally enhancing appearance. They also tend to remodel bone (Fig. 6-117). On MR imaging, they have low to intermediate signal intensities on all imaging sequences and enhance minimally.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is one of the most common soft-tissue sarcomas below the clavicles. While it has been recognized that MFH has become a ''waste-basket'' category for some sarcomas, there is a group of sarcomas that truly reveal both fibroblastic and histiocytic phenotypes. Only about 3% occur in the head and neck, and most of these occur in the skin, orbit, or sinonasal cavities.[185, 234, 235]

A number of histologies, either uniform or a mixture of patterns, may be seen in MFH, which can be histologically classified as myxoid, angiomatoid, inflammatory, and giant cell type. Most MFHs have a storiform/pleomorphic pattern. Whorls and fascicles of malignant fibroblastic spindle cells forming a ''rush-mat'' or radiating ''star-like'' (storiform) pattern characterize MFH. The putative ''histiocytic'' component is composed of plump epithelioid cells and larger multinucleated giant cells that have bizarre nuclei. If a prominent myxoid background is present, these sarcomas

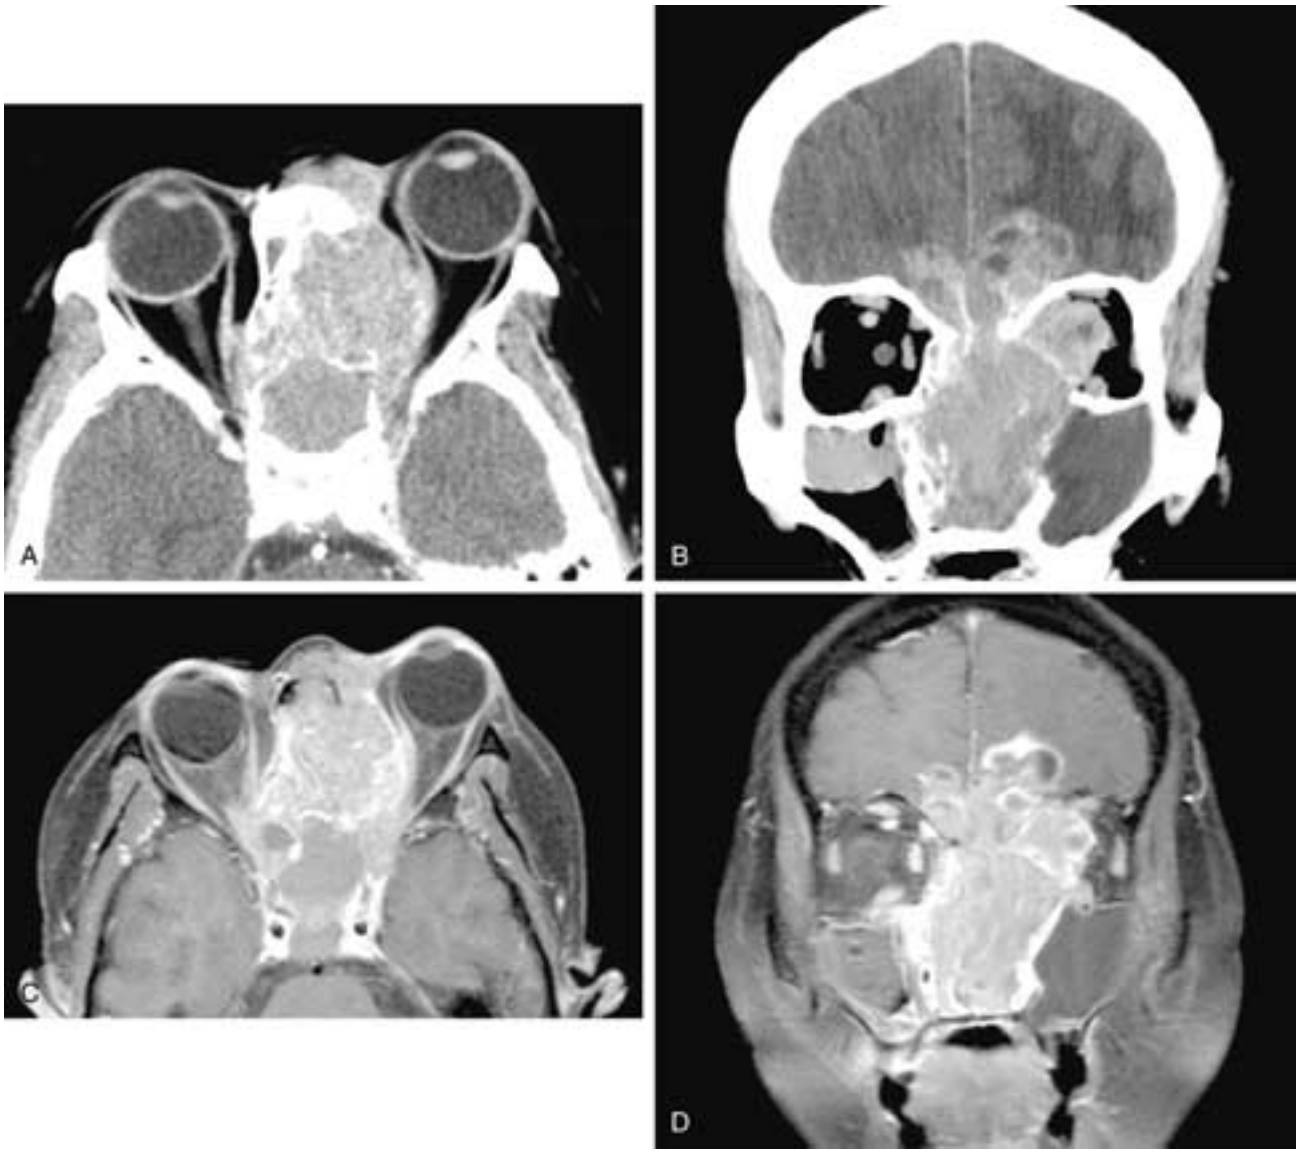

FIGURE 6-116 Axial (**A**) and coronal (**B**) contrast-enhanced CT scans show a destructive mass that has broken into the anterior cranial fossa and invaded the brain. The tumor also has extended into both orbits and obstructed the left antrum. Incidental inflammatory disease is present in the right maxillary sinus. Axial (**C**) and coronal (**D**) T1-weighted, contrast-enhanced MR images confirm the disease mapping and the presence of a sphenoid sinus mucocele. Statistically, in a 45-year-old male, this imaging appearance should suggest the diagnosis of squamous cell carcinoma. This patient had a rhabdomyosarcoma.

can be classified as myxoid MFH. As with other sarcomas, focal metaplastic mesenchymal elements such as cartilaginous or osseous differentiation may be seen in MFH. A marked inflammatory infiltrate may be present, thus warranting the designation of *inflammatory MFH.*

MFHs express vimentin diffusely; other markers, such as desmin, may be seen focally. The immunohistochemical pattern of MFH also has many nonspecific markers: antibodies to lyzozyme, alpha-1 antitrypsin, and acid phosphatase mark some MFHs. Nemes and colleagues have shown that FXIIIa, a marker of histiocytes and pericytes, can be expressed in MFH and in HPC.[236] Therefore, strong, diffuse expression of FXIIIa in the right circumstances may support the diagnosis of MFH.[237]

The 2-year survival rate for all MFHs is 60%. Local recurrences develop in 27% of cases, 75% within 2 years of diagnosis. Cervical nodal metastases occur in 12% and distant metastases in 42% of cases. Of the eight nasopharyngeal carcinoma survivors with secondary sinonasal MFH, none were disease free at follow-up and six died of disease without distant metastasis within 30 months.[185]

On contrast CT, these tumors usually enhance moderately and either aggressive bone destruction or bone remodeling can occur, making the CT characteristics nonspecific (Fig. 6-118).[238, 239] On MR imaging, fibrous histiocytomas usually have intermediate signal intensities on all imaging sequences, and contrast enhancement may be nonhomogeneous.

Benign Fibrous Histiocytoma

Benign fibrous histiocytoma (dermatofibroma) is a histologically benign lesion with fibroblastic and histiocytic components that most commonly occurs in the dermis and subcutis. It has been reported anecdotally as a sinonasal lesion.[240] Histologically, fibrous histiocytomas are composed of whorls of benign fibroblastic cells with a radiating, storiform pattern admixed with multinucleated giant cells. They can be distinguished from MFH, as they are less cellular and lack nuclear pleomorphism, abnormal mitotic figures, and necrosis.

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumor (IMFT) (also referred to as inflammatory pseudotumor and plasma cell granuloma) is a poorly understood ''emerging'' entity that manifests as a space-occupying lesion composed of a benign lymphoplasmacytic and myofibroblastic infiltrate. In the head and neck, IMFT most often affects the periorbital and orbital soft tissue. It has also been described in the supraglottic larynx and the salivary glands. At least 17 cases have been reported involving the sinonasal tract, nasopharynx, pterygomaxillary space, and parapharyngeal space. These have occurred over a wide age range from childhood (3 years) to old age (the ninth decade). In the sinonasal tract, they present as polypoid masses causing nasal obstruction. Maxillary sinus involvement may result in a soft tissue mass with bony erosion and remodeling.

In the parapharyngeal and pterygomaxillary spaces, IMFT can cause trismus and pain. Systemic symptoms such as fever, weight loss, malaise, anemia, hypergammaglobulinemia, and elevated sedimentation rate may also be present. It is quite common for patients with IMFT to undergo multiple biopsy procedures in order to establish a diagnosis.[241–248]

On biopsy evaluation, IMFT appears to be a diagnosis of exclusion. Excised tumors have been described as fleshy, whorled, and firm or myxoid. The polymorphous appearance of IMFT may reflect its variable etiology or its shifting histology during disease course. Lymphocytes, plasma cells, histiocytes, fibroblasts, and myofibroblasts are the basic components of IMFT, with mutable proportions. Four basic histologic patterns have emerged: (1) a dominant lymphoplasmacytic infiltrate, (2) a dominant lymphohistiocytic infiltrate, (3) a predominantly ''young and active'' myofibroblastic process, and (4) and a predominantly collagenized process with a lymphoplasmacytic infiltrate. Lymphoplasmacytic IMFT consists of a mature lymphoid infiltrate with germinal centers and a rich plasma cell infiltrate—hence the name plasma cell granuloma. Lymphohistiocytic IMFT most closely resembles an infectious process, as foamy histiocytes are prominent. The ''young and active'' IMFT has a

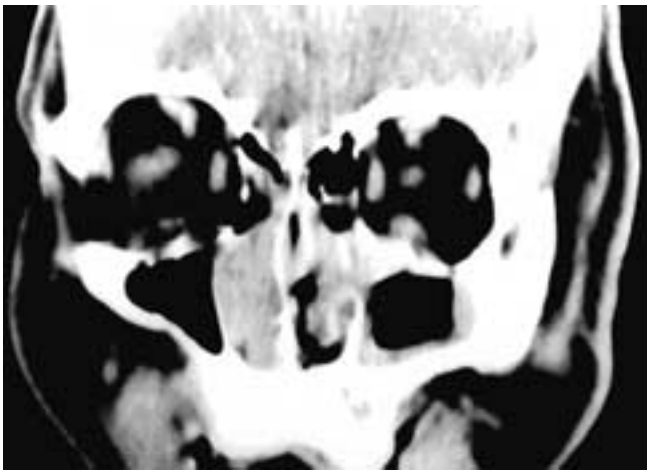

FIGURE 6-118 Coronal CT scan shows an expansile polypoid mass in the right nasal fossa (*arrowhead*). There is no bone erosion, and the nasal septum is intact. Inflammatory disease is present in the left antrum and nasal cavity. This patient had a fibrous histiocytoma.

densely cellular fascicular and storiform pattern resembling that of fibrous histiocytoma, except for the inflammatory infiltrate or nodular fasciitis (see Chapter 41 for a discussion of nodular fasciitis, which characteristically arises from superficial fascia and presents as a freely movable subcutaneous nodule). Overlapping histologic features between IMFT, nodular fasciitis, and fibrous histiocytoma corroborate the place of these entities in the pathologic spectrum between reactive and neoplastic processes. Collagenized IMFT is paucicellular and resembles a desmoid tumor, but with a prominent inflammatory infiltrate, and a zonation/maturation effect may be observed. Progression of patterns may also be seen in some long-standing cases necessitating multiple procedures.[241–248]

IMFTs of solid organs (e.g., lung, liver) are resected for diagnostic purposes and so effectively treated. Coffin et al. reported single or multiple recurrences in 25% of patients after initial excision; two cases progressed to sarcomatous transformation. However, the recurrent or transformed cases still showed a tendency to remain localized.[244] Recurrence was more often seen in patients with mesenteric or retroperitoneal tumors. In head and neck sites, including the sinonasal tract, most IMFTs do resolve/regress with excisional biopsy and steroid therapy; however, some IMFTs may persist and worsen, requiring more aggressive therapy such as radiotherapy.[241–248]

Solitary Fibrous Tumor

Solitary fibrous tumor (SFT) is an uncommon spindle-cell neoplasm derived from primitive mesenchymal or fibroblast-like cells. First recognized as a pleural neoplasm (fibrous mesothelioma), SFT has gained greater recognition and has been described in other soft tissues, including the head and neck.[249–251]

In the sinonasal tract, SFT presents as a firm, polypoid, well-circumscribed or encapsulated soft-tissue neoplasm. Histologically, SFT is composed of bland spindle cells arranged in a ''pattern-less pattern''; focally storiform or fascicular growth patterns or hemangiopericytoma-like vascular patterns are seen. Collagen deposition to the point of keloid-like hyalinization can be seen. Myxoid areas and rich vascularity are present, with hyalinized vessels. The tumor boundary may be circumscribed or infiltrative. Immunohistochemically, SFT expresses vimentin, CD34, and CD99. SFT is usually cured by resection; recurrences or progression to higher-grade tumors (mitotic figures, necrosis, pleomorphism, increased cellularity) are rare.

Fibromyxoma and Myxoma

A number of other benign or low-grade neoplasms can develop from pleuripotential mesenchymal cells, producing fibromyxoid and myxoid tumors. These tumors are related to fibroosseous lesions; however, they contain no osseous or odontogenic matrix. Fibromyxomas and myxomas tend to occur during the second and third decades of life.

Radiographically, fibromyxomas are soft-tissue, primarily expansile masses when they involve the sinuses, although focal areas of aggressive bone destruction may be present. These lesions usually have flecks or thin strands of calcification dispersed within the tumor substance (Figs. 6-119 and 6-120).

Histologically, one sees bland stellate fibroblastic cells producing myxoid stroma. A variable collagenizing component may be present. Sinonasal fibromyxomas can be locally aggressive, with a significant recurrence rate, especially if treated by curettage.[219] Therefore, complete surgical excision is the treatment of choice.

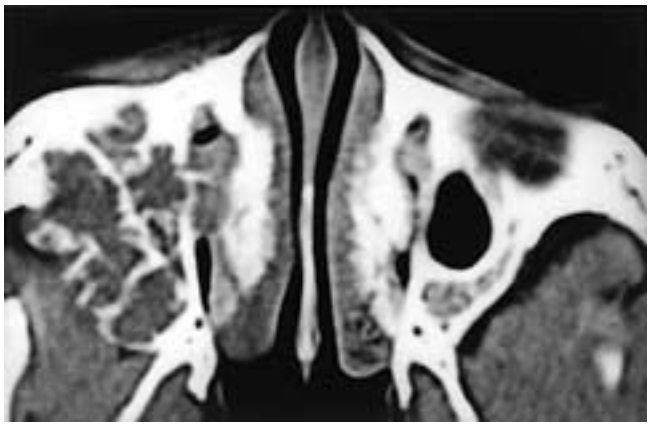

FIGURE 6-119 Axial CT scan shows a partially destructive and partially expansile mass in the right maxillary sinus. The lesion contains lacelike areas of calcification. This patient had a fibromyxoma.

VIEW IMAGE

A myxoma is a benign mesenchymal tumor composed of undifferentiated stellate cells producing a myxoid stroma. These tumors are generally uncommon and have been reported in the heart (atrial myxoma), subcutaneous tissues, bone, genitourinary tract, and skin. Head and neck myxomas are usually intraosseous; those of the jaws represent 40% to 50% of all head and neck myxomas. Mandibular myxomas have been presumed to arise from odontogenic tissue and hence are also called odontogenic myxomas. Those that arise from the maxillary bone may extend to the maxillary sinus and nasal cavity.[252] On CT they are cystic-appearing lesions that do not enhance (Fig. 6-121).[253]

BENIGN AND MALIGNANT OSSEOUS LESIONS AND TUMORS (INCLUDING FIBROOSSEOUS LESIONS)

Of the nonepithelial tumors that involve the sinonasal cavities, nearly 25% are osseous or fibroosseous lesions. These lesions and tumors can be categorized as lesions of abnormal bone development causing tumoral masses (Paget's disease, fibrous dysplasia, cemento-ossifying dysplasia, cherubism, giant cell reparative granuloma), benign osseous tumors (osteoma, osteochondroma, exostosis, osteoid osteoma, osteoblastoma, ossifying fibroma, chondroma, giant cell tumor), and malignant tumors (chondrosarcoma, osteogenic sarcoma).

Benign Tumors

Osteoma and Exostosis

Osteoma is a benign expansile proliferation of mature bone that occurs within bone. Exostosis is a benign, expansile proliferation of mature bone that occurs on the surface of bone. When an exostosis projects intracranially

Copyright © 2003, Mosby, Inc. All rights reserved.

from the calvarium, it is also referred to as an enostosis. Osteomas are found almost exclusively within the membranous bones of the skull and face, most commonly within the frontal sinuses, followed by the ethmoid sinuses. Maxillary and sphenoid sinus osteomas are rare. The high prevalence of frontal and ethmoid sinus osteomas may be related to the fact that these sites represent the junction of membranous and enchondral development of the frontal and ethmoid bones.[254]

Osteomas of the sinuses are not uncommon and may be seen in up to 1% of radiographs obtained for sinus symptoms. Sinus osteomas may be asymptomatic, or patients may complain of headache, sinus symptoms, or a frontal mass. They obstruct the frontal sinus in 17% of cases, resulting in the need for immediate surgery (Fig. 6-122).[209] They can also obstruct the lacrimal apparatus.[255] Almost all osteomas remain confined to the sinuses, often conforming to the contour of the sinus. However, osteomas are also the

Axial T1-weighted (**B**), axial T2-weighted (**C**), and axial (**D**) and coronal (**E**) T1-weighted contrast-enhanced MR scans on a different patient show a large mass destroying part of the right maxillary alveolus and expanding and filling the left maxillary sinus, elevating and thinning the orbital floor. There is no infiltration of the orbit. The teeth roots are exposed by the tumor, and the tumor is fairly homogeneous in signal intensity. This patient had a myxoma.

VIEW IMAGE

most common benign paranasal sinus tumors associated with spontaneous CSF rhinorrhea, pneumocephalus, and tension pneumocephalus (Figs. 6-123 and 6-124).[256–258] Osteomas tend to grow slowly; the mean growth rate has been estimated at 1.61 mm/yr (range, 0.44 to 6.0 mm/yr) in a series of 13 patients with successive sinus radiographs.[259]

Multiple osteomas can be a manifestation of Gardner's syndrome, a very rare autosomal dominant transmitted disorder consisting of (1) intestinal polyposis with progression to intestinal adenocarcinoma, (2) benign skin and subcutaneous neoplasia, such as epidermoid inclusion cysts and desmoid tumors, and (3) multiple osteomas, with a proclivity for the mandible. These osteomas can arise within the second decade of life and precede intestinal polyps, which are usually diagnosed after the third decade of life (Figs. 6-125 and 6-126).

Exostoses occur in the external auditory canal (''swimmer's ear'') or on the palate or mandible (torus palatini or torus mandibularis). The latter usually presents as a painless bulging of the alveolus, possibly causing dentures to fit poorly (Fig. 6-127). Torus palatinus (Fig. 6-128) is seen in the hard palate, at the junction of the left and right horizontal plates of the palatine bones and the palatine processes of the maxilla.

Osteomas usually are small, incidental findings on plain films, where they have a variable bone density, ranging from very dense and sclerotic, for the ivory-type osteoma, to a progressively less dense and less ossified lesion for the

VIEW IMAGE

fibrous osteoma (Figs. 6-129 to 6-133). In fact, some fibrous osteomas may be confused on plain films with a retention cyst or polyp. On CT, osteomas arise from one of the sinus walls or the intersinus septum. The differences between the compact, cancellous, and fibrous types of osteoma correlate with the degree of bone matrix density seen within the lesion. On MR imaging these lesions give a nonhomogeneous, low to intermediate signal intensity on all imaging sequences. Based purely on MR imaging findings, their osseous nature may go undetected (Fig. 6-123).

Pathologically, osteomas are composed of dense, hard, mature bone, with only small amounts of fibrous tissue. The cancellous, or mature, osteoma has sparse intertrabecular spaces that may be empty or filled with fat, fibrous tissue or hematopoietic elements. Fibrous osteomas contain abundant mature lamellar bone, with greater amounts of intertrabecu-

lar fibrous tissue. Exostoses are seen as compact layers of dense cortical bone without a medullary component.

Osteochondroma

An osteochondroma is a benign cartilage-capped osseous growth arising from the surface of bone. They represent 35% to 50% of benign osseous lesions and 8% to 15% of all osseous tumors.[254] They are believed to represent a developmental abnormality rather than a neoplastic process. Osteochondromas arise from any bone developing via enchondral ossification. Because the craniofacial bones are membranous, sinonasal osteochondromas are rare. The mandible (coronoid process and condyle) was the most common site (52%) of 63 head and neck ''osseous'' osteochondromas reported in the literature.[254] They have also been reported rarely in the sphenoid bone, maxillary tuberosity, zygomatic arch, and nasal septum. Most osteochondromas have a limited growth potential; expansion ceases with axial skeletal maturation. However, some osteochondromas may continue to grow after skeletal maturation.

Radiographically, these tumors tend to have a pedunculated mushroom shape. The cartilaginous cap is often not visible and, when seen, may be focally calcified. On MR imaging, the tumors have a nonhomogeneous low to intermediate signal intensity on all imaging sequences (Figs. 6-134 and 6-135).

VIEW IMAGE

VIEW IMAGE

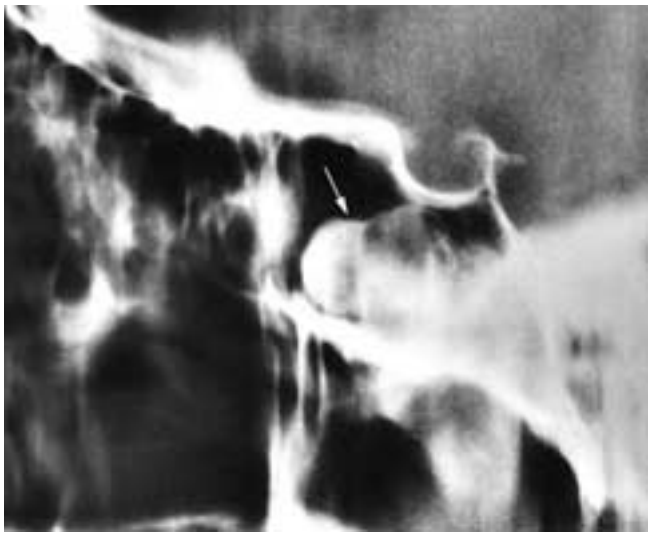
FIGURE 6-133 Lateral view shows an osteoma in the sphenoid sinuses.

Pathologically, cortical and cancellous bone, with a cartilaginous ''cap,'' are seen. This ''cap'' may become atrophic with time. Simple resection is the treatment of choice, and only 1% to 2% of lesions recur. Similarly, only 1% to 2% of solitary osteochondromas undergo malignant change, usually to chondrosarcomas.

Chondroma

Chondromas are completely benign cartilaginous tumors. The definition of chondromas may vary with the tumor site, and there may be no absolute criteria distinguishing chondromas from grade I chondrosarcomas in some confined areas, such as the larynx. However, no diagnosis of ''chondroma'' should be accompanied by radiologic evidence of destruction or histologic evidence of pleomorphism. It is well appreciated that lack of pleomorphism on a limited biopsy does not rule out the possibility of a grade I or higher chondrosarcoma. The majority of head and neck chondromas (70%) have been reported in the nasal cavity and ethmoids. Others may occur in the maxilla, sphenoid sinuses, palate, and nasopharynx. There is no sex predilection, and about 60% occur in patients less than 50 years of age.[254] Wide surgical excision with negative margins is the treatment of choice.[260, 261]

On CT, calcifications within the tumor matrix are not always seen. These lesions tend to be expansile, remodel bone, and have an attenuation less than that of muscle but greater than that of fat.[262, 263] They do not provoke sclerotic bone at their margins. On MR imaging, they usually have low T1-weighted and high T2-weighted signal intensities, and they enhance. The imaging findings are not specific.



VIEW IMAGE

FIGURE 6-134 Lateral multidirectional tomogram shows a partially ossified, pedunculated mass in the sphenoid sinus (*arrow*). This patient had an osteochondroma.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma is a benign expansile neoplasm characteristically associated with nocturnal pain. It represents 11% of benign bone neoplasms, with a male-to-female ratio of 2:1. The majority of patients are diagnosed between 5 and 25 years of age, and the femur and tibia are the most commonly affected bones. In 26 culled literature cases of the head and neck, the mandible and cervical vertebrae were the most common sites.[254] Osteoid osteomas have been rarely reported in the frontal, ethmoid, and maxillary bones. Patients describe a dull pain that usually worsens at night, intensifies with activity, and is relieved by rest and aspirin.

On plain films and CT, the classic lesion is a dense cortical ovoid mass with a 1 to 2 mm low-density nidus. However, the nidus also may be dense and difficult to identify radiographically.[254] Histologically, the nidus is recognized as a tangled array of new osteoid bony trabecula surrounded by reactive bone. The intertrabecular tissue is vascular and fibrotic. Simple excision or curettage is curative.

Osteoblastoma (giant osteoid osteoma) is a benign expansile lesion representing only 3% of all benign bone tumors. There is a peak incidence in the second decade of life, with a male-to-female ratio of 2:1. The most common

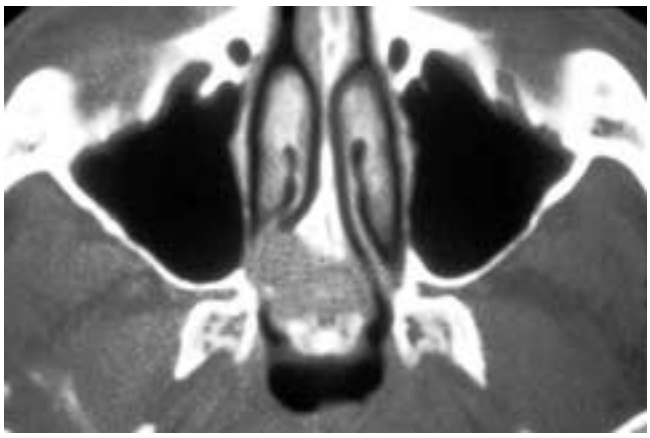


FIGURE 6-135 Axial CT scan shows an expansile, partially calcified mass in the posterior nasal septum. This patient had an osteochondroma.

VIEW IMAGE

sites of occurrence are the vertebral column (34%) and the long bones of the appendicular skeleton (30%). However, osteoblastomas are more likely to involve the head and neck (15% of 364 cases) than are osteoid osteomas.[264] The mandible is the most common site (usually the mandibular body), followed by the cranium and maxilla. Ethmoid and sphenoethmoid osteoblastomas have also been reported.[254] Patients present with a painful mass; however, the pain does not have the consistent pattern encountered with osteoid osteoma (nocturnal and relieved with aspirin).

Radiographically, osteoblastomas tend to be expansile and remodel adjacent bone. They range from 2 to 10 cm in diameter; in contrast, the nidus of osteoid osteomas is invariably less than 1 cm. Osteoblastomas have a variable radiographic appearance; some lesions have large, discrete areas of organized bone density, and others have a mixed osseous and fibrous appearance. The latter tends to be more nodular and more coarsely organized than most ossifying fibromas and some fibrous dysplasias (Figs. 6-136 and 6-137).[256, 265, 266]

Pathologically, osteoblastomas are virtually identical to osteoid osteoma. Histologically, one sees interconnecting trabeculae of osteoid or woven immature bone. The term *aggressive osteoblastoma* (juvenile aggressive osteoblastoma) is reserved for recurrent tumors or those with histologic atypia. Histologically, these lesions have a denser population of epithelioid osteoblasts, with prominent mitotic activity and multifocality.[267] At times, the distinction between aggressive osteoblastoma and a well-differentiated osteogenic sarcoma may be difficult. Conservative surgery, consisting of local excision or curettage, cures 80% to 90% of the cases of benign osteoblastoma. Aggressive osteoblastomas recur locally but do not metastasize.[254]

Ossifying Fibroma (Cemento-Ossifying Fibroma)

Ossifying fibroma (OF) is a benign expansile tumor occurring most commonly in tooth-bearing regions in the second or third decade of life, with a female predominance. OF arises from the periodontic ligament, most commonly in the molar or premolar regions of the mandible, followed by the maxilla.[254] Many synonyms exist for this tumor (cemento-ossifying fibroma, fibroosseous lesion, psammomatoid ossifying fibroma, etc.), reflecting its ability to produce a variable matrix. Patients present with a painless, solitary expansile mass.

OF can also arise in the nasal cavity, usually from the lateral nasal wall or ethmoid complex. If it is sufficiently large, OF can affect the frontal, sphenoid, and maxillary sinuses.

Radiographically, OF appears as an expansile, circumscribed tumor with well-defined borders. The surrounding bone appears normal. The internal organization of OF reveals discrete zones of either variable osseous or fibrous tissue. CT usually reveals large, nonossified areas of fibrous tissue density, in contrast to fibrous dysplasia (FD).[255] Ideally, FD can be distinguished from OF by its noncircumscribed nature, as it ''blends'' into relatively abnormal bone, and its propensity for multiostotic involvement. However, some cases of OF may be indistinguishable from FD on CT imaging. The MR imaging appearance of OF can be quite variable, depending on the composition of this lesion.[268]

Pathologically, OF is composed of densely cellular, well-circumscribed fibrous tumor. Ossification, or cementoossification, commences at the periphery. The ossification is composed of immature woven bone that matures into lamellar bone. This is unlike FD, in which bony trabeculae are produced throughout the lesion but are highly atypical, without maturation or normalization. Cementum formation is seen as acellular coalescing spherical calcifications that have distinctive basophilic perimeters.

OF is optimally treated by conservative surgical excision, although larger tumors may require more aggressive resection. Compared with the clinical behavior of FD, which can remain stable, OF has a greater tendency to behave aggressively (grows faster and recurs more quickly after surgery) and to expand internally toward the orbits, nasal fossae, and sinus cavities rather than to deform the outer surface bones (Figs. 6-138 to 6-141).[269] Tension pneu-

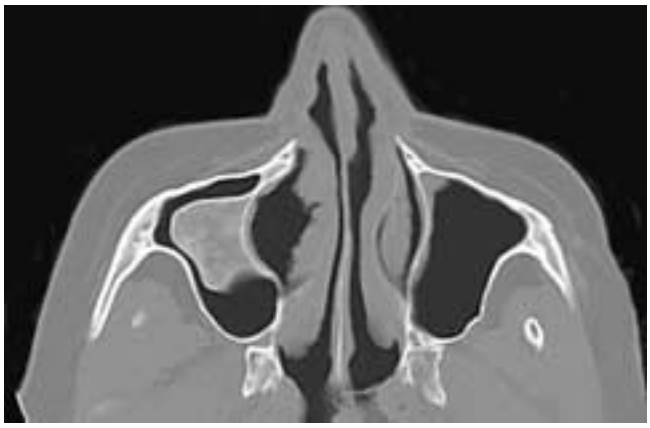
mocephalus has been reported as an uncommon complication of an OF.[270]

Tumor-Like Conditions and Giant Cell–Rich Lesions

Fibrous Dysplasia

Fibrous dysplasia (FD) is an idiopathic skeletal disorder in which medullary bone is replaced by poorly organized, structurally unsound fibroosseous tissue. Most patients are under 30 years of age at diagnosis.[271] The majority of cases (75% to 80%) are limited to the monostotic form (MFD), which most often involves the ribs or femur. The craniofacial bones may be involved in monostotic FD in up to 25% of cases; most commonly affected are the maxilla and mandible.[272] Polyostotic FD (PFD) comprises 20% to 25% of all cases. Usually there is unilateral bone involvement, but in severe cases bilateral disease can occur. The



VIEW IMAGE

FIGURE 6-139 Axial CT scan shows a ''ground glass'' bony mass projecting into the right maxillary sinus cavity. There is a surrounding cortex. This patient had an ossifying fibroma.

craniofacial bones are more often (40% to 50%) involved in PFD.[271, 272]

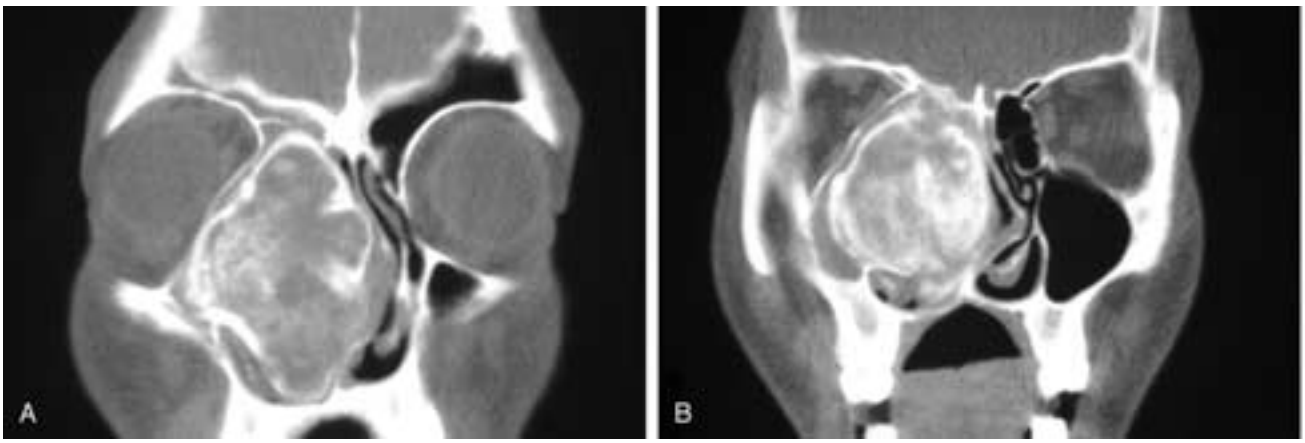
Albright's syndrome consists of PFD plus pigmented skin macules and sexual precocity. This syndrome is relatively rare. It is 40 times less common than MFD, and it occurs almost exclusively in females. The skin pigmentations have irregular margins (''coast of Maine''), as opposed to the smoother-bordered pigmentations (''coast of California'') of neurofibromatosis.

Patients with craniofacial FD involvement usually present with asymmetric cheek swelling.

Encroachment into the paranasal sinuses, nasal fossae, orbit, or neurovascular canals can lead to nasal obstruction, headaches, and visual disturbances. Recently, it has been appreciated that involvement of the frontal and sphenoid sinuses by FD can result in mucoceles. Extensive maxillary involvement results in facial distortion, referred to as leontiasis ossea (''lion face'').

New FD lesions usually do not develop after the growth plates have fused. Some lesions, however, continue to grow after skeletal maturation.

Histologically, FD appears as irregular, disformed bony trabeculae of immature woven bone, which are thinned, C-



VIEW IMAGE

or S-shaped, and referred to as *Chinese characters.* The trabeculae are embedded in, and blend into, vascularized fibrous tissue lacking the osteoblastic rimming of normal bone. Serial biopsies over time do not reveal maturation of this woven bone into lamellar bone.[271] Surgery is used only to correct deformities, relieve pain, correct functional problems, decompress a mucocele, or resect sarcomas. FD recurs in 20% to 30% of cases, usually within 2 to 3 years of initial therapy.[271]

Malignant transformation of bone with FD is very rare (less than 1% of cases). In a review of 83 sarcomas complicating FD, 57% of the patients had MFD and 43% had PFD. The craniofacial bones are most commonly involved, and irradiation may promote malignant transformation. The average latency period from diagnosis of FD to development of malignancy is 13½ years. The majority of these tumors are osteogenic sarcomas, followed by fibrosarcomas and chondrosarcomas.[271]

The radiologic appearance varies according to the degree of fibrous tissue present. Thus, the bone texture can range from a nonhomogeneous mixture of bone and fibrous tissues to a predominantly fine, bony ''ground glass'' appearance. The disease expands the diploic or medullary space and widens the bone. A thin, intact rim of cortical bone is often seen over the margins of the involved bone. MR imaging usually shows a low to intermediate signal intensity on all imaging sequences, and often the cortical bone overlying the medullary disease can be identified as a zone of low signal intensity. There usually is intense enhancement with contrast. If areas of high T2-weighted signal intensity are present within an obstructed or involved sinus, the presence of a mucocele should be considered (Figs. 6-142 to 6-153).[273, 274] Because there is often an overlap in the imaging appearance of FD and ossifying fibroma, the term *benign fibroosseous lesion* has been suggested to describe the imaging findings of both lesions.[275]

Cemento-Ossifying Dysplasia

There are a number of cementum-containing lesions that may affect the jaws. Periapical fibrous dysplasia (periapical cemental dysplasia) produces lytic and then blastic expansile periapical lesions, usually affecting the lower anterior jaw. The etiology is unknown. It is usually seen in patients more than 20 years of age and is more prevalent in African Americans.[271] The lesions are usually smaller than 1 cm. Radiographically, early lesions appear as periapical radiolucencies. As cementum or osteoid is produced, central calcification is seen radiographically, which becomes more

FIGURE 6-143 Caldwell view shows a dense expansile lesion of the left frontal and zygomatic bones that has encroached on the left orbit. This patient had fibrous dysplasia.

dense and uniform as the lesion matures. Focal cemento-osseous dysplasia is characterized by the formation of an expansile cystic lesion, which usually occurs in the posterior mandible. It may occur in dentulous or edentulous bone.

There is a pronounced female predominance, with a peak incidence in the fourth and fifth decades. Radiographically, one sees an expansile cystic lesion that may or may not be associated with a tooth and can be either lucent, opaque, or mixed density, possibly with a sclerotic rim.

Florid cemento-osseous dysplasia appears to be a diffuse form of periapical cemental dysplasia. It is characterized by the development of multiple expansile jaw tumors containing cementum or osteoid. These lesions affect the lower jaw more commonly than the upper jaw and may be symmetric. Black middle-aged women are most commonly affected. Radiographically, the lesions are cystic, mixed lytic/blastic.

Cherubism

Cherubism (familial multilocular cystic disease of the jaw, hereditary fibrous dysplasia) is a nonneoplastic disease limited to the jaws and characterized by bilateral, painless jaw enlargements that are said to give the patient a cherubic appearance. Cherubism may appear sporadically or be familially transmitted. It is inherited in an autosomal dominant fashion, with high (nearly 100%) penetrance in males and variable (50% to 75%) penetrance in females. The disease appears between the ages of 6 months and 7 years and is characterized by bilateral fullness of the jaws. The eyes appear to look up as the lower sclera are exposed. The disease often develops rapidly until age 7 years and then gradually regresses. The mandible is involved first, followed by the maxilla in about two thirds of the cases. Most of the radiographic changes occur in the mandible, where expansile cystic masses are seen in the angles and ramus. As the disease progresses to the maxilla, the sinus opacifies and the orbital floor may be bulged upward. The latter finding is one of the causes of the upward-looking eye of cherubism.[276] Pathologically, one sees proliferating fibrous connective tissue with numerous multinucleated giant cells indistinguishable from those of giant cell reparative granuloma. The disease is self-limited and is usually diagnosed after the age of 2 years. Treatment is usually not necessary, but if embarked on for cosmetic or other reasons, it will not provoke regrowth of lesional tissue.[277–279]

True Giant Cell Tumor

Giant cell tumor (GCT) of bone (previously referred to as osteoclastoma) is an uncommon, benign, yet potentially locally aggressive tumor that comprises up to 5% of all primary bone neoplasia. More than 75% of these tumors are located in the epiphyseal region of long bones, half of them occurring about the knee. There is a female predisposition, and the majority of affected patients are beyond the second decade of life. GCT of the head and neck is extraordinarily rare.[271, 280] Huvos identified 3 GCTs of the cranium and maxilla out of 265 GCTs treated at the Memorial Sloan-Kettering Cancer Center.[280] Kujas and colleagues identified only seven cases of true GCT of the skull and cervical vertebrae after reviewing neuropathology specimens collected over 50 years.[281] An association

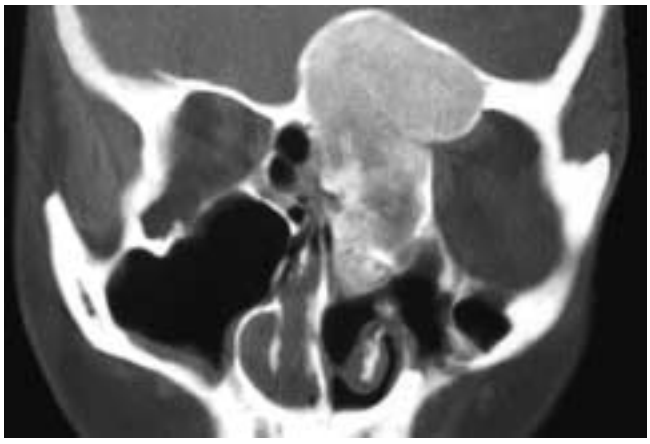
FIGURE 6-146 Axial serial CT scans (**A** through **D**) through the facial region show that all of the facial and skull base bones are greatly expanded, with intact cortices. Their medullary spaces are filled with ossified and nonossified regions. The skull base foramina, orbital apices, and paranasal sinuses are all obliterated. The mandible is also affected. This patient had fibrous dysplasia.

between GCT of the jaws and Paget's disease has also been noted.[280]

Histologically, GCTs are characterized by a diffuse population of osteoclastic giant cells spread across a background of short spindled cells with nuclei identical to those within the giant cells. This latter point allows for distinction between GCT and the myriad other osteoclastic giant cell–rich lesions that may affect bone. There may be dozens to hundreds of nuclei within the osteoclastic giant cells. Identification of these gargantuan benign giant cells also aids in establishing the diagnosis. Hemorrhage and hemosiderin deposition are not prominent features of GCTs. Reactive bone may be seen in the periphery of the tumor, as the ossified cartilage may undergo some remodeling. The differential diagnosis of GCT of the head and neck includes central giant cell reparative granuloma (CGCRG), ''brown tumor'' of hyperparathyroidism, or, more rarely, giant cell–rich osteogenic sarcoma. The distinctions between these entities may be impossible to make on a biopsy without radiographic and clinical correlation (Fig. 6-154).



VIEW IMAGE

FIGURE 6-147 Coronal CT scan shows a localized region of expanded bone in the left frontal and ethmoid bone. The medullary space has a ''ground glass'' appearance, and the cortices are intact. This patient had fibrous dysplasia.

There is considerable demographic (age of diagnosis) and histologic overlap between GCT and CGCRG, so that these two entities may represent a spectrum of a single disease process that is modified by patient age and site of occurrence.[282, 283]

The treatment of choice is complete surgical excision or curettage. The recurrence rate for GCT at all sites is 30% to 50% after curettage. Most local failures occur within 2 years of initial therapy.[284] Approximately 10% to

Notice the similarity to **A**. This patient had an intraosseous meningioma.

15% of GCTs show clinical or histologic evidence of malignancy. Malignancy can occur de novo or as secondary transformation. Almost all secondary malignant transformations have been previously irradiated. Radiation therapy should be reserved for surgically inaccessible tumors, as GCTs are generally not radiosensitive and as radiation therapy is accompanied by the threat of malignant transformation.

On CT the tumors enhance moderately, and they tend to destroy and remodel bone.[285, 286] On MR they usually have fairly low signal intensity on all sequences, and they enhance.

Giant Cell (Reparative) Granuloma

Giant cell (reparative) granuloma (GCG) is an entity of uncertain etiology that may affect either the jaw bones

FIGURE 6-150 Axial T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, contrast-enhanced MR images (**C**) and an axial CT scan (**D**) show a polypoid right posterior nasal cavity mass that has low T1-weighted and intermediate T2-weighted signal intensity and diffusely enhances. The CT scan shows the lesion to have an intact bony cortex and nonossified central regions. This patient had fibrous dysplasia.

(central giant cell granuloma [CGCG]) or the intraoral soft tissues (peripheral giant cell granuloma [PGCG]). The term *reparative* was originally introduced by Jaffe, but recently this modifier has been dropped from the name, as there is no evidence to support this function. PGCG is four times more common than CGCG. PGCG presents as an expansile mass of the gingiva or alveolar mucosa that rarely extends to the underlying bone. It occurs over a broad age range, with a peak incidence in the fourth decade of life. PGCG may occur after tooth extraction or with ill-fitting dentures and therefore may be related to trauma. There is a female predisposition, which implies hormonal sensitivity.

CGCG presents as an expansile, destructive intraosseous jaw mass. There is also a female predisposition, but the majority of patients present prior to the fourth decade of life. There is no association with prior trauma.

Radiographically, PGCG rarely is clearly visualized. However, CGCG typically appears as a multiloculated, expansile lytic lesion on plain film (Fig. 6-155).[185, 285–288] On CT, CGCG is bulky and enhancing and can be seen to aggressively erode the maxillary sinus walls or to have an expansile, remodeling apearance. On MR imaging, CGCG has an intermediate signal intensity on both T1-weighted and T2-weighted images. As such, the MR appearance may mimic that of SCC.[241]

Pathologically, GCG characteristically has a hemorrhagic, fibroblastic background with innumerable osteoclastic giant cells. This background is helpful in distinguishing GCRG from GCT. The latter lacks the diffuse hemorrhage, hemosiderin, and fibroblasts, and the background cells are identical to the nuclei of the osteoclastic giant cells. The giant cells of GCT are diffusely and evenly dispersed throughout the tumor. In contrast, the brown tumor of hyperparathyroidism has uneven clumps of osteoclasts, perivascular hemorrhage, and hemosiderin deposition.

It is useful to know the serum calcium and parathyroid hormone levels when dealing with any giant cell lesion. In hyperparathyroidism the calcium level is elevated unless the patient is already severely calcium depleted. Serum parathyroid homone (PTH) is elevated with a brown tumor of hyperparathyroidism and is normal with other GCTs. PTH is also normal in tumor-induced osteomalacia, which radiologically can mimic severe hyperparathyroidism.[289] Giant cell granuloma arising in the skull base is discussed in Chapter 12.

Aneurysmal Bone Cyst

An aneurysmal bone cyst (ABC) is neither an aneurysm nor a true cyst, but it does occur in bone. Rather, it is a benign, nonneoplastic, expansile osseous lesion. ABC occurs mainly in females over the age of 20 years and represents only 1% to 2% of all primary bone tumors. It can

Copyright © 2003, Mosby, Inc. All rights reserved.

present as a slowly or rapidly enlarging mass with nonthrobbing pain. ABCs may occur de novo; however, they may be ''engrafted upon'' (occur in conjunction with) another primary osseous tumor. This process may be pathologically identified in as many as one third of ABCs; the most common findings are GCT, unicameral bone cyst, or nonossifying fibroma.[284] Between 3% and 12% of ABCs occur in the head and neck, and they have also been reported in the maxilla, orbit, ethmoid, and frontal bones.[290] In a review of 64 reported cases of jaw ABC, the ratio of mandibular to maxillary cases was 2.4:1, with a predisposition for the posterior mandible. There was a wide age range, with a median age of 17 years.[291] Primary paranasal sinus/nasal cavity ABC has rarely been described and has been seen in conjunction with preexisting primary bone pathology.[292, 293]

Histologically, ABCs are composed of large, variably sized, blood-filled cystic and sinusoidal nonendothelium-lined spaces traversed by fibroblastic cells. New bone formation is evident; osteoid formation, osteoclast giant cells, and plump background spindle cells are seen. Hemorrhage and hemosiderin deposits are present. Surgical resection or curettage is the treatment of choice; in the jaws,

currettage has a somewhat higher recurrence rate (20% to 38%) than resection (11% to 25%).[284]

Radiographically, this lesion may be unilocular or may demonstrate a multilocular ''soap bubble'' or ''honeycomb'' radiolucency (Fig. 6-156). Kaffe and colleagues found that the majority of cases were radiolucent (87%), mixed (11%), or radiopaque (2%); the radiographic appearance was less common.[291] Fifty-three percent were multilocular, 43% were unilocular, and 3% were not loculated. The peripheral bone margins were defined but not corticated in 39%, well defined in 33%, and diffuse in 28%. Bony remodeling and destruction can be seen (Fig. 6-157). On MR imaging, the classic findings are those of multiple cysts with fluid-fluid levels (Figs. 6-158 and 6-159).

Paget's Disease

Paget's disease (osteitis deformans) is a bone disorder of unknown etiology. Increased osteoclastic and osteoblastic activity results in the disorderly production of abnormally dense yet mechanically fragile bone. The disease usually occurs in patients over 50 years old, and its incidence increases with age, ranging from 3% to 5% of people older than 40 years to 11% of those older than 80 years.[294] There is a male predominance and some familial predisposition. The disease is usually (90%) polyostotic and involves the vertebrae (76%), calvaria (65%), pelvis (43%), femur (35%), and tibia (3%). In the head and neck, the clavaria, maxilla, and mandible are most commonly affected.[295] In 80% of patients, the degree of skeletal involvement is limited and found fortuitously on radiographic studies or at autopsy. The facial bones are rarely involved; however, whenever the maxilla and mandible are affected, the calvarium is invariably also involved.[295] Advanced calvarial involvement may lead to a characteristically enlarged head, and the reduced size of the cranial cavity secondary to calvarial and skull base bony ingrowth can lead to altered mental status, dementia, and other neurologic abnormalities. Platybasia is associated with cranial nerve deficits. Encroachment into the orbits, neurovascular canals, and sinonasal cavities has led to proptosis, visual loss, neurologic deficits, facial deformity, and nasal congestion. Despite the thickness of the bone, it is extremely vascular and fragile and may be prone to fracture.

The initial radiographic and CT appearance of Paget's disease of the calvarium often reveals a lytic phase that produces osteoporosis circumscripta, usually involving the frontal region to the greatest degree. A ''mixed'' phase may follow. This phase shows foci of sclerotic, woven bone

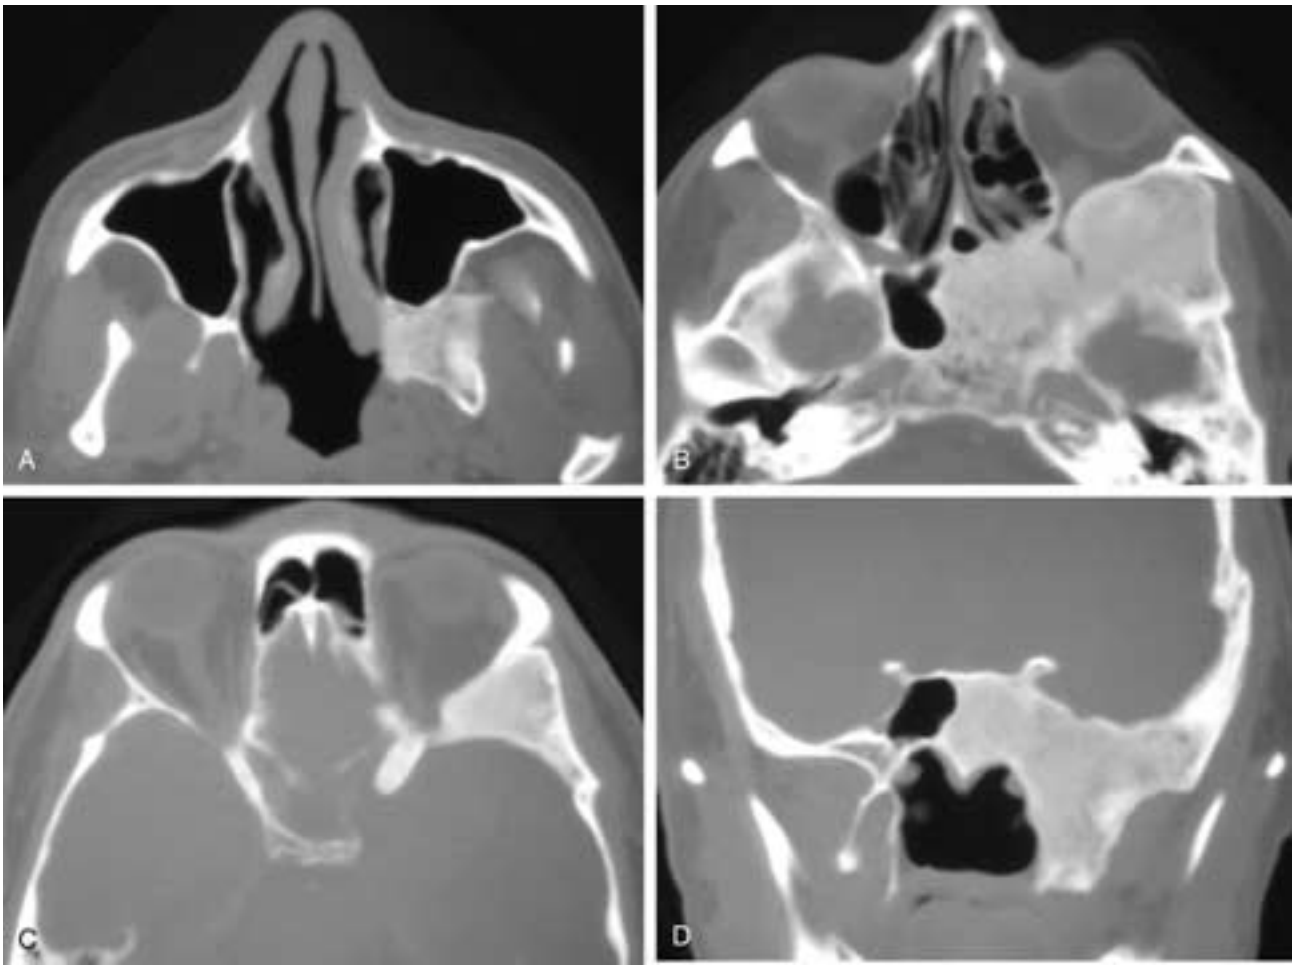

FIGURE 6-152 Serial axial CT scans (**A** through **C**) and coronal CT scans (**D**) show a ''ground glass'' expanded left sphenoid bone. The left sphenoid sinus is obliterated, and all portions of the bone are affected.

FIGURE 6-152 *Continued.* Axial T1-weighted (**E**), T2-weighted (**F**), and T1-weighted, contrast-enhanced (**G**) MR images and a coronal T2-weighted (**H**) MR image show the low to intermediate T1-weighted and T2-weighted signal intensity and the marked enhancement of the process. This patient had fibrous dysplasia.

within areas of lower density, which represent sites of fibrous myeloid production. The remaining bone often gives a moderately diffuse radiopacity producing a ''cotton wool'' appearance. Eventually, there can be a sclerotic phase, with poor corticomedullary differentiation. The calvarium itself is thickened; usually the greatest degree of thickening is anterior, and one side of the skull tends to be more affected than the other. Inner table irregularity is usually greater than that of the outer surface. It is the sclerotic form of Paget's disease that usually affects the facial bones. This results in a thickened, dense bone with slightly irregular cortical surfaces and poor corticomedullary differentiation (Figs. 6-160 to 6-163).[295]

On MR imaging, the dense foci of bone give rounded foci of signal void on all imaging sequences. The marrow tissues give high T1-weighted and fairly high T2-weighted signal intensities, reflecting the fat and blood protein in these regions. The background matrix gives an intermediate signal intensity on all imaging sequences. The facial area demonstrates a mixed, low to intermediate signal intensity on all imaging sequences. The lesion usually enhances nonhomogeneously.[295]

Histologically, pagetoid bone reflects an erratic resorption pattern and new production of bone that fails to mature normally. This is seen as predominantly woven mosaic bone, with increased osteoclastic and osteoblastic activity.

Sarcomas may develop in 5% to 10% of patients with multifocal Paget's disease and in less than 2% of patients with limited bone involvement. The prognosis of Paget's sarcoma is grave; most patients die within 2 years. The development of multiple tumors is frequent; autopsy studies suggest a multicentric rather than a metastatic origin for these tumors. Most Paget's sarcomas are osteogenic sarcomas (50% to 60%) or fibrosarcomas (20% to 25%).[296] In the facial area, benign GCTs can also occur. On plain films and CT, GCTs usually appear as sharply localized, nonosseous masses. Because the bone seen in Paget's disease, as well as in the sarcomas, tends to give an intermediate signal intensity on all MR imaging sequences, it is often more difficult to diagnose and map these malignancies or tumors on MR imaging than on CT (Fig. 6-163).[295]

Sarcomas

Osteogenic Sarcoma and Chondrosarcoma

Primary bone sarcomas occur over a wide age range; osteogenic sarcoma (OS) occurs most commonly after the

Copyright © 2003, Mosby, Inc. All rights reserved.

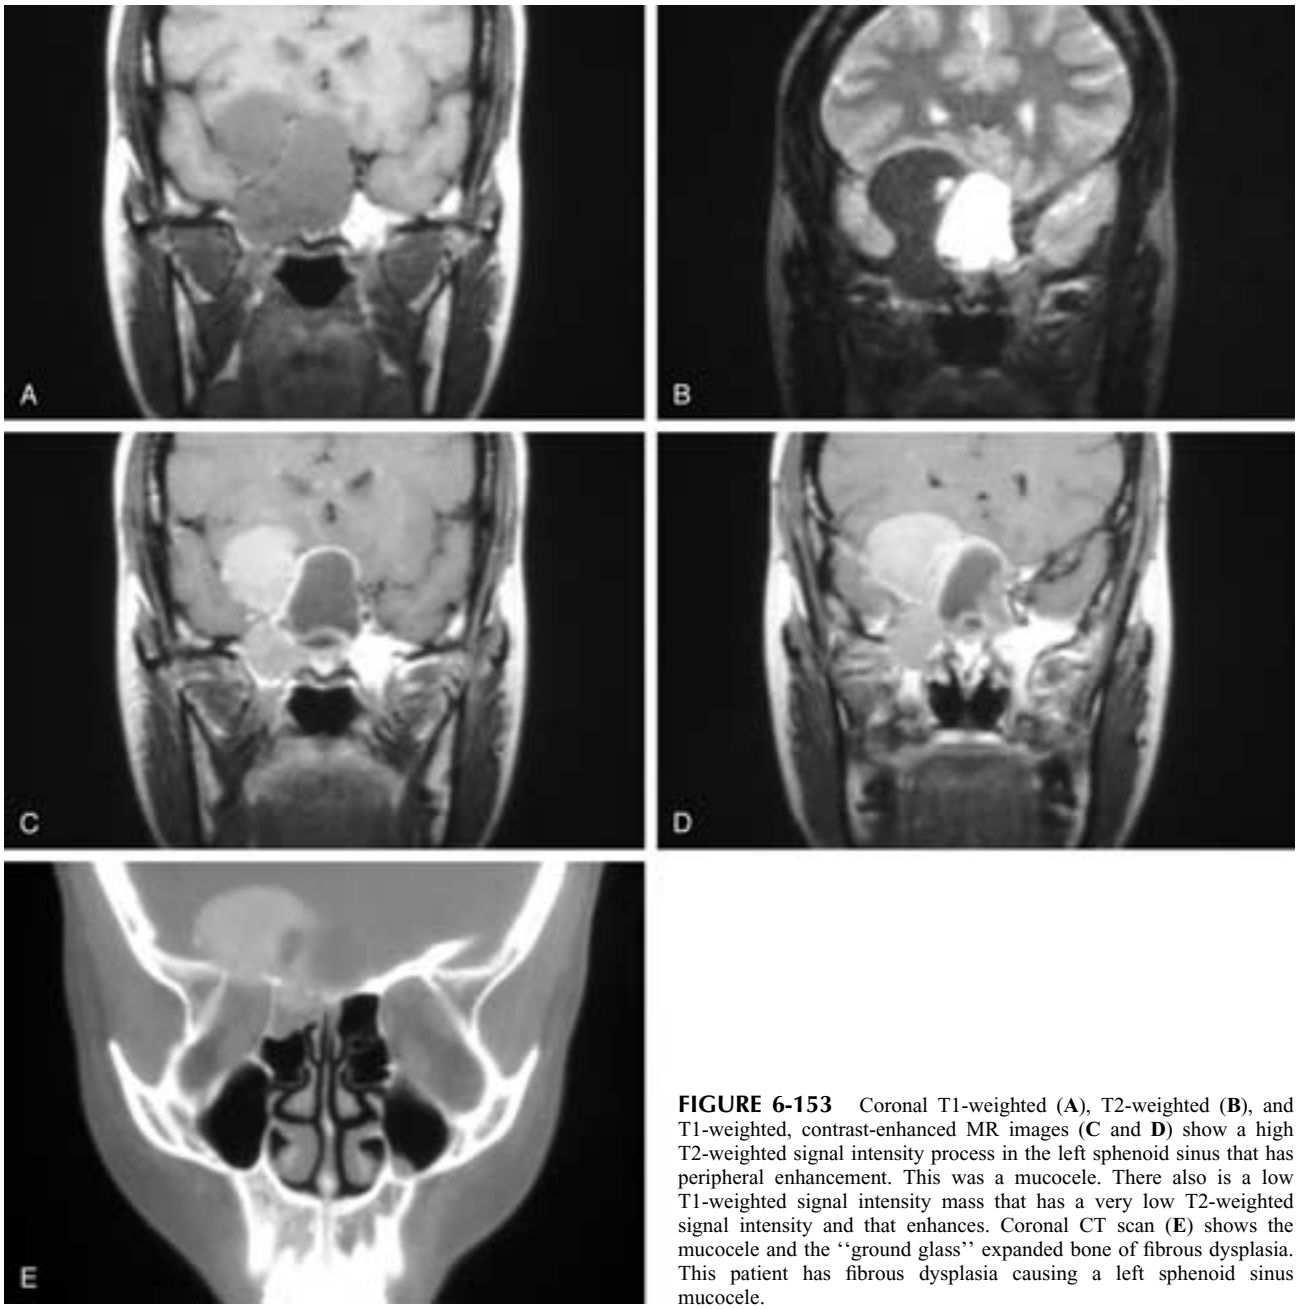

FIGURE 6-153 Coronal T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, contrast-enhanced MR images (**C** and **D**) show a high T2-weighted signal intensity process in the left sphenoid sinus that has peripheral enhancement. This was a mucocele. There also is a low T1-weighted signal intensity mass that has a very low T2-weighted signal intensity and that enhances. Coronal CT scan (**E**) shows the mucocele and the ''ground glass'' expanded bone of fibrous dysplasia. This patient has fibrous dysplasia causing a left sphenoid sinus mucocele.

VIEW IMAGE

first decade of life, whereas chondrosarcoma (CS) occurs most commonly after the fourth decade. Primary OS, that is, OS in the absence of previous irradiation or Paget's disease, most commonly occurs prior to closure of the growth plates within the distal femur. Huvos reported on over 1000 cases of OS from Memorial Sloan-Kettering Cancer Center and found that half of them occurred around the knee, and that the femur was the most common bone affected.[297] Only 7% of these OSs occurred in the head and neck, usually in the jaws (55 of 77 cases in the head and neck, followed by craniofacial bones and calvaria).

Primary CSs occur most commonly in the pelvic region and femur.[298]

In a series of almost 500 CSs from Memorial Sloan-Kettering Cancer Center, only 5% (25 cases) occurred in the head and neck. Secondary CS of the head and neck can be seen after radiation therapy or in the setting of Maffucci syndrome or Ollier disease.[299] In a review of 56 craniofacial CSs, 25 (44.6%) involved the alveolar maxilla and maxillary sinus; 23 (41.1%) involved the nasal septum, ethmoid, and sphenoid; 6 (10.7%) involved the mandible; and 2 (3.6%) involved the nasal tip.[300–302]

Histologic diversity characterizes OS. OS, by definition, is a tumor in which the malignant cells produce an osteoid matrix. Histologic subtypes of OS include (1) osteoblastic OS, which produces abundant osteoid matrix; (2) chondroblastic OS, which produces abundant chondroid matrix, yet the osteoid present merits the classification of OS rather than CS; (3) telangiectatic OS, a highly vascular sarcoma with a lytic radiographic appearance; (4) fibroblastic (fibrosarco-

FIGURE 6-154 Coronal (**A**) and axial (**B**) CT scans show a densely ossified mass in the nasal septum. Two months earlier, this was a nonossified mass. This patient had a healed brown tumor from hyperparathyroidism.

matous) OS, composed predominantly of malignant fibroblast-like cells with some osteoid production; (5) fibrohistiocytic (malignant fibrous histiocytoma [MFH]) OS, which contains malignant multinuclear tumor giant cells in addition to the fibrosarcomatous component; and (6) round cell OS, composed predominantly of small round malignant cells with occasional osteoid production (Fig. 6-164). Many OSs display multiple histologic patterns, thereby precluding neat categorization. Despite the wealth of clinicopathologic data, there is little to indicate that histologic subclassification for OS has prognostic significance over classic tumor staging and grading (Broder's grading) schemata.

CS is generally more histologically uniform than OS. Abundant chondroid matrix is the rule. CS is graded (I, II, III) according to tumor cellularity and cytologic atypia.

VIEW IMAGE

FIGURE 6-159 Axial T2-weighted MR image shows a mass in the sphenoid bone and sphenoid sinus. This lesion is composed of multiple cystic areas, each with a fluid-fluid level. This patient had an aneurysmal bone cyst.

Grade I CS is composed of invasive lobulated tumor producing abundant matrix, with binucleate chondrocytes (Fig. 6-165). Distinguishing it from a benign chondroma may not be possible with limited material and requires radiographic correlation to establish an aggressive, invasive growth pattern. Grade II CS has greater cellularity and pleomorphism than a grade I tumor and is easily identified as both malignant and chondroid in nature. A grade III neoplasm is very cellular and pleomorphic. The chondroid matrix may be limited. Spindle cell CS (so-called dedifferentiated CS) is an unusual variant in which a high-grade undifferentiated sarcoma ''springs forth'' from a lower-grade CS.

Surgery and adjuvant chemotherapy is indicated for OS. Establishing a preoperative diagnosis of OS allows for neoadjuvant chemotherapy. The chemotherapeutic effect can then be histologically assessed based on postoperative (postchemotherapy) tumor viability, and thus the postoperative completion of chemotherapy can be tailored based on the observed response. Complete surgical resection is indicated for CS; adjuvant chemotherapy and radiotherapy have not been shown to improve survival. Proton beam therapy may be considered as primary therapy for unresectable cases. Survival of patients with head and neck OS and CS is dependent upon tumor stage, grade, and site. Jaw OS has a 5-year disease-free survival rate of between 30% and 50%. The prognosis for OS in Paget's disease, as mentioned, is known to be particularly poor. The 5-year disease-free survival rate for craniofacial CS is around 40%.[303] Fu and Perzin emphasize that sinonasal CS is less amenable to resection than CS at other sites.[209] For both OS and CS, the metastatic rate (predominantly to the lungs, liver, brain, bones, and lymph nodes) directly correlates with the tumor grade. Overall, only 7% of sinonasal CSs develop metastases. Patients with mesenchymal CS in general have a 5-year survival rate ranging from 42% to 54.6% and a 10-year survival rate of 28%. Mesenchymal CS of the jaw bones (5- and 10-year survival rates of 82% and 56%, respectively) appears to have a more indolent course than axial skeletal or soft tissue mesenchymal CS.[304, 305]

On imaging, CS tends to occur at the cartilaginous junctions of the facial bones or in the cartilaginous nasal septum. Marginal bone erosion is typically present, and calcifications within the mass may or may not be seen. These tumors have fairly low T1-weighted and high T2-weighted signal intensities, and they enhance after contrast administration, either uniformly or nonuniformly. Without the presence of gross tumoral calcifications, the imaging appearance is not characteristic enough to establish a definitive diagnosis (Figs. 6-166 to 6-172). Rarely, a large, aggressive pituitary adenoma that extends into the nasal fossa may have similar imaging findings (Fig. 6-173).

With OS, there typically is a ''sunburst'' periosteal reaction, although this need not be present. Focal destruction is usually seen; however, dense sclerotic bone may be present, especially in the maxillary alveolus. Depending on the bone content of the tumor, the signal intensities can vary, usually being primarily a low T1-weighted and an intermediate T2-weighted signal intensity. Enhancement after contrast administration is present, although not usually to the degree seen in CS (Figs. 6-174 to 6-180).

Mesenchymal Chondrosarcoma

Mesenchymal CS is a rare variant of CS, representing approximately 10% of all CSs.[306] It can occur as an osseous (60% to 70%) or soft tissue (30% to 40%) neoplasm. Among 35 patients with mesenchymal CS seen at the Memorial Sloan-Kettering Cancer Center, 14% occurred in the head and neck, most commonly in the maxilla.[306] The craniospinal meninges and orbital soft tissues are the most common extraskeletal sites. These tumors also have been reported in the ethmoid sinuses. The majority of affected patients are 40 years old or younger (average, 26 years old). Mesenchymal CS is a bimorphic tumor composed of islands of well-differentiated hyaline cartilage juxtaposed to a small cell undifferentiated malignancy.

ODONTOGENIC LESIONS AND TUMORS

Odontogenic and developmental cysts arise from the cystic expansion of epithelial remnants of various components of the dental apparatus or entrapped epithelium. They are generally uncommon entities and can be classified as either follicular cyst, periodontal cyst, odontogenic keratocyst, calcifying odontogenic cyst, nasopalatine cyst, median palatine cyst, and nasolabial cyst. The following discussion is limited to those jaw cysts that can present as maxillary or palatal lesions (also see Chapter 17).

Jaw Cysts

Follicular Cyst

Follicular cysts (also referred to as dentigerous cysts) represents up to 24% of all odontogenic cysts. There is a pronounced predisposition for males and for African Americans. Most affected patients are diagnosed between the second and fourth decades of life. These cysts develop as

VIEW IMAGE

a result of fluid accumulation either around the tooth crown or within the enamel organ. They are invariably associated with impacted or unerupted teeth. The most commonly affected teeth are the mandibular third molars, maxillary canines, and third molars. Follicular cysts may also be associated with supernumerary teeth.[307]

Radiographically, one sees a well-circumscribed cyst that contains the crown of the tooth. As the cyst grows, it pulls the unerupted tooth with it. Small dentigerous cysts are unilocular. Large cysts may be multilocular, and the confined tooth may be displaced from its normal location. Resorption of adjacent teeth roots can occur.[308]

The dentigerous cyst must be distinguished radiographically from a normal dental follicle. If a dental follicle measures 2 cm or more, it is highly likely that the unerupted tooth will develop a dentigerous cyst. Similarly, a pericoronal space of 2.5 mm or more heralds an 80% likelihood that the unerupted tooth will become a dentigerous cyst.[309]

If the cyst erodes into the maxillary sinus, it may grow rapidly, remodeling the antral walls. Often the inferior maxillary sinus cortex is elevated over portions of the cyst. In the axial view, this can be detected by noting what appear to be two bony walls in the posterior sinus. Here the most posterior bone represents the true sinus wall, while the anterior bone represents the elevated sinus floor. If multiple dentigerous cysts are present, the patient should be examined for the basal cell nevus syndrome (see below). On MR imaging, the cyst fluid has intermediate signal intensity

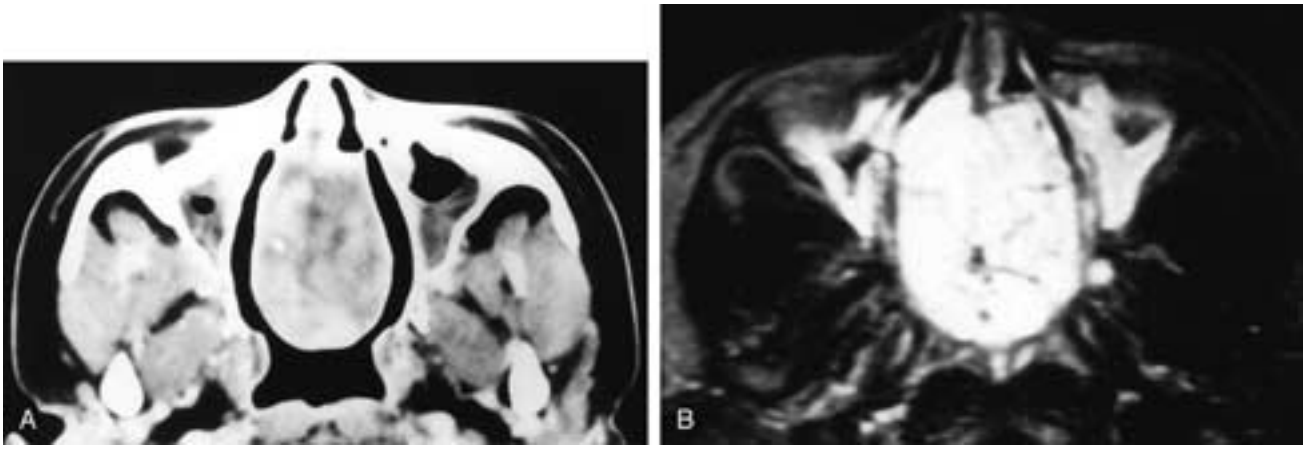

FIGURE 6-168 Axial CT scan (**A**) and axial T2-weighted MR image (**B**) show a bulky mass arising from the nasal septum. Scattered calcifications are present within the mass. The lesion had an intermediate T1-weighted signal intensity. Obstructive inflammatory changes are present in the maxillary sinuses. This patient had a chondrosarcoma.

FIGURE 6-169 Sagittal T1-weighted (**A**) and T2-weighted (**B**) MR images show a slightly nonhomogeneous nasal septal mass that has a low to intermediate signal intensity in **A** and a high signal intensity in **B**. The frontal sinuses are obstructed by the tumor. This patient had a chondrosarcoma.

on T1-weighted images and high signal intensity on T2-weighted images; the displaced tooth gives a signal void on all imaging sequences. In this regard, the MR imaging appearance may be similar to that of an antral aspergilloma (Figs. 6-181 to 6-186).

Small dentigerous cysts are cured by curettage. Larger multiloculated cysts may require marsupialization. An ameloblastoma may arise within the wall of the dentigerous cyst. This mural or cystic ameloblastoma is often diagnosed only by the pathologist; the radiographic findings in such cases are those of a simple dentigerous cyst.[307, 309] There is a familial predisposition toward this transformation. The prognosis of a cystic ameloblastoma arising in a dentigerous cyst is excellent, as curettage is usually curative.

FIGURE 6-170 Sagittal T1-weighted, fat-suppressed, contrast-enhanced MR image shows an enhancing nasal septal mass that has extended into the sphenoid bone. A mucocele is present within the obstructed sphenoid sinus. This patient had a chondrosarcoma.

Periodontal Cyst

Periodontal cysts are also referred to as periapical, radicular, apical periodontal, or dental cysts. They represent the most common jaw cyst and arise in erupted, infected carious teeth as sequelae to periapical granulomas. Maxillary teeth are most commonly involved. Maxillary periodontal cysts can erode into the maxillary sinus, remodeling the antral walls and elevating the inferior sinus cortex (Figs. 6-187 to 6-189).[309, 310]

The term *residual periodontal cyst (residual cyst)* refers to a periapical cyst developing after tooth extraction. Treatment of these cysts consists of simple enucleation.[306]

The lateral periodontal cyst (also referred to as a paradental cyst) is a noninflammatory developmental cyst that arises lateral to the tooth root. This cyst probably arises from proliferation of rests within the dental lamina. This cyst occurs most often in adults in the premolar and cuspid areas. Radiographically, there is an incidental multiloculated cyst along the lateral tooth root.

Odontogenic Keratocyst

Odontogenic keratocysts (OKCs) can be subclassified as central (intraosseous), which are further subclassified as parakeratotic, orthokeratotic, or mixed, versus peripheral or mucosal. The central parakeratotic OKC (POKC) is most commonly encountered and is also referred to as a primordial cyst. POKC represents up to 16.5% of all jaw cysts and is most commonly seen in patients within the second and third decades of life. The mandible is affected two to four times more often than the maxilla, with a predilection for posterior jaws. Half of patients with POKC

This appearance is highly suggestive of a sarcoma rather than a carcinoma. This patient had an osteogenic sarcoma.

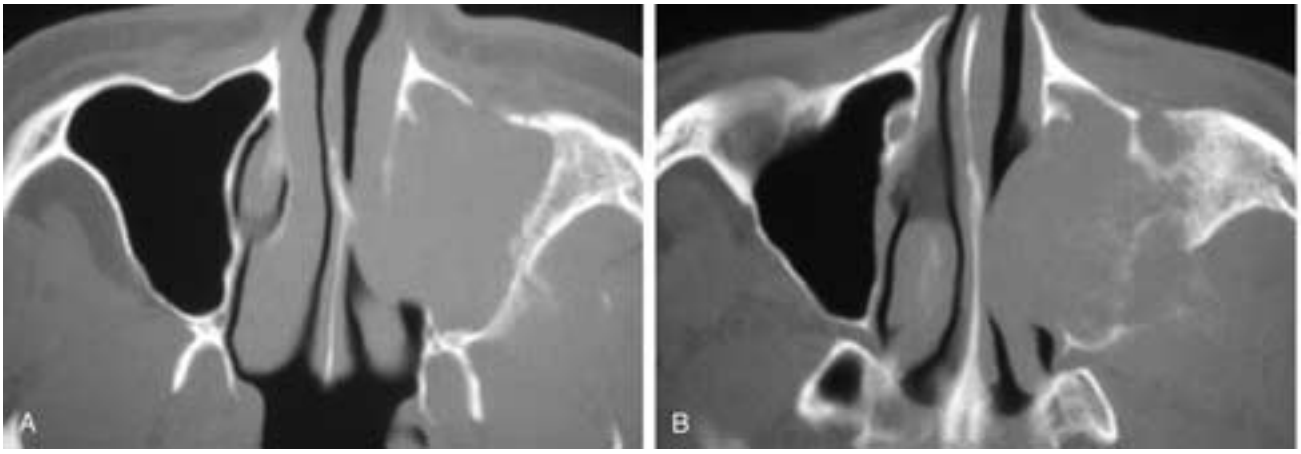
complain of pain. Maxillary POKC can extend into the antrum, causing nasal obstruction.[307]

Historically, the term *primordial cyst* reflects the idea that these cysts were derived from degenerated stellate reticulum of the enamel organ prior to mineralization. However, these cysts are now believed to originate from dental lamina or its remnants or from extensions of basal cells from the overlying epithelium. Most are believed to develop from supernumerary teeth. When a rare cyst develops in place of a tooth, it is considered a replacement type of keratocyst.[307]

Radiographically, POKCs appear as unilocular or multilocular radiolucencies that may have a thin, reactive, sclerotic bony rim and smooth or scalloped margins or appear destructive, invading adjacent bone. Pathologically, these cysts are lined by stratified squamous epithelium, producing corrugated parakeratosis. The term *parakeratosis* refers to retained nuclei within the compact hyperkeratosis. The basal reserve cells reveal reverse palisading, which refers to the fact that the nuclei are oriented away from the basement membrane.

Multiple odontogenic keratocysts are associated with the nevoid basal cell carcinoma syndrome (Gorlin's syndrome). This condition is transmitted in an autosomal dominant fashion as a result of loss of a tumor suppressor gene on chromosome 9q22. Nevoid basal cell carcinoma syndrome is associated with the early development of multiple basal cell carcinomas, which can occur within preexisting sebaceous nevi, palmar and plantar pitting, and skeletal developmental abnormalities, as well as within the above-mentioned POKC. POKCs have also been associated with Marfan's syndrome. They are known for their aggressive potential for invasion and recurrence; up to 62.5% may recur. Simple POKC may be treated by enucleation, keeping the cyst intact. Multilocular or more destructive POKCs are better treated by en bloc resection.

Orthokeratosis is defined as compact keratin without retained nuclei. An orthokeratotic-type keratocyst (OOKC) represents 13% of OKCs. There is a male predisposition and no increased predominance in African Americans. OOKCs have a predilection for the mandible, but unlike POKCs, OOKCs are more likely to affect the anterior jaws. OOKCs are noteworthy in that they are generally unilocular.[307]



VIEW IMAGE

VIEW IMAGE

Radiographically, one sees a unilocular radiolucent cyst. CT shows the bone morphology better than plain films; however, contrast-enhanced MR images provide the essential macroscopic detail, including focal wall enhancement and isointense intraluminal soft-tissue masses, which correlates with the histologic findings of focal inflammatory ulceration of the cyst lining, orthokeratosis, and cell debris. The cyst lining lacks the prominent corrugated proliferating basaloid reserve cells of POKC. Rather, these basal reserve cells are more flattened. The hyperkeratosis lacks retained nuclei, hence the classification ''orthokeratosis.'' Curettage is curative. OOKCs are less aggressive than POKCs and recur infrequently.

Calcifying Odontogenic Cyst

This cyst has a variety of names, including keratinizing ameloblastoma, keratinizing and calcifying ameloblastoma, melanotic ameloblastic odontoma calcifying cyst, cystic calcified odontogenic tumor, ghost cell tumor, and atypical adamantinoma.[307] The calcifying odontogenic cyst is an uncommon lesion, comprising only about 2% of all benign odontogenic lesions.[307] These cysts affect the maxilla and mandible equally. About 78% are intraosseous (central), and 22% are confined to the peripheral soft tissues. They are either unilocular or multilocular radiolucent cysts that frequently contain radiopaque material ranging from small flecks to large masses. The lesion can be well circumscribed or poorly demarcated. Radiographically, it resembles a calcifying epithelial odontogenic tumor, an odontoma, an ossifying fibroma, and fibrous dysplasia. The lining of a calcifying odontogenic cyst consists of ameloblastic epithelium and ''ghost cells,'' which undergo dystrophic calcification. Treatment can be by curettage, enucleation, or conservative surgical excision; unlike the keratocyst, recurrences are unlikely.[310]

Fissural Cyst

The term *fissural cyst* refers to a cystic expansion that had been attributed etiologically to entrapped epithelium within

VIEW IMAGE

the fusion lines of the frontonasal and maxillary processes. However, it is apparent that these rare cysts may actually result from a variety of inflammatory as well as developmental etiologies. These cysts are classified as either globulomaxillary or median mandibular cysts.[307] Figure 6-190 is a diagrammatic overview of all of the cysts related to the maxillary alveolus and the palatal region.

The globulomaxillary cyst is found between the maxillary lateral incisor and canine teeth and represents less than 3% of all jaw cysts and 20% of maxillary cysts. Most occur in patients under 30 years of age. Radiographically, the globulomaxillary cyst appears as an inverted pear-shaped or ovoid cyst in the maxillary alveolus (Fig. 6-191). It often pushes apart the roots of the lateral incisor and canine teeth and can distort the lower anterior aspect of the maxillary sinus.[309]

Radiographically, the median mandibular cyst appears as a well-circumscribed radiolucency between the mandibular central incisors. The histologies of both cysts are nonspecific, and the diagnoses are confirmed radiographically.

Developmental Cyst

Developmental cysts are the most commonly encountered nonodontogenic jaw cysts, representing 73% of these cysts.[307] They develop from entrapped ductal epithelium and may be classified anatomically as either nasopalatine duct (also known as median anterior maxillary cysts), median palatal, or nasolabial cysts (Figs. 6-190, 6-192, and 6-193). Nasopalatine or median anterior maxillary cysts may be further subclassified as either incisive canal cyst (ICC) or palatine papilla cyst. The latter cyst is uncommon, derived from the incisor papilla soft tissue, and does not manifest itself radiographically. The ICC is thought to arise from remnants of the nasopalatine duct or as a result of degeneration of the contents of the incisive canal.[307] Patients with ICC present with a swelling of the anterior palate behind the central incisors.

Radiographically, ICC appears as a well-defined radiolucency above or between the root apices of the maxillary central incisors, exceeding 0.6 cm, that does not extend into the paranasal sinuses.[307] The cyst may be lined by either squamous or respiratory mucosa and may contain glandular or connective tissue remnants.

The median palatal cyst is an ICC that has extended posteriorly. Clinically, it appears as a midline palatine swelling that may also extend to the nasal floor. Radiographically, it appears as a midline palatal radiolucency. The histology is similar to that of ICC.

Lastly, the nasolabial (also referred to as nasoalveolar) cyst is thought to be derived from the nasolacrimal duct apparatus. Clinically, it appears as a small cystic mass in the upper lip, nasal vestibule, or nasal alae, obliterating the

Copyright © 2003, Mosby, Inc. All rights reserved.

nasolabial fold. Nasolabial cysts are primarily soft-tissue based and therefore are rarely seen on plain films. If large, they may scallop the adjacent bone.

Odontogenic Tumors

Odontogenic tumors arise from the dental apparatus, mimicking the various stages of odontogenesis; ameloblastoma, cementoma, odontoma, and fibromyxoma are the most common of these tumors, which can involve the paranasal sinuses (also see Chapter 17).

Ameloblastoma (Including Unicystic Ameloblastoma)

Ameloblastoma represents only 1% of all pathologic lesions of the jaw and 18% of all odontogenic tumors.[307] Characteristically, this is a slowly growing solid and cystic tumor. Most affected patients are in the third and fourth decades of life. The ratio of mandibular to maxillary tumors is approximately 4:1, and the posterior mandible is the most common site. The majority of maxillary tumors (90%) involve the premolar-molar area. Noncentral ameloblastomas (those arising from peripheral, soft-tissue, nonosseous, or noncentral sites) are not considered in this discussion. An ameloblastoma presents as an enlarging, painless swelling, and large maxillary tumors can cause nasal obstruction. Other signs and symptoms include pain, bleeding, unhealed extraction sites, trismus, and neural involvement.[311, 312]

Radiographically, the ameloblastoma appears as a multiloculated, honeycombed lytic lesion devoid of mineralization. If the tumor extends into the antrum, the sinus will be clouded and the walls remodeled or destroyed. On CT, ameloblastomas have a nonenhancing, nonhomogeneous appearance, and on MR imaging they have nonhomogeneous mixed signal intensities. On T1-weighted images these tumors demonstrate intermediate signal intensity,

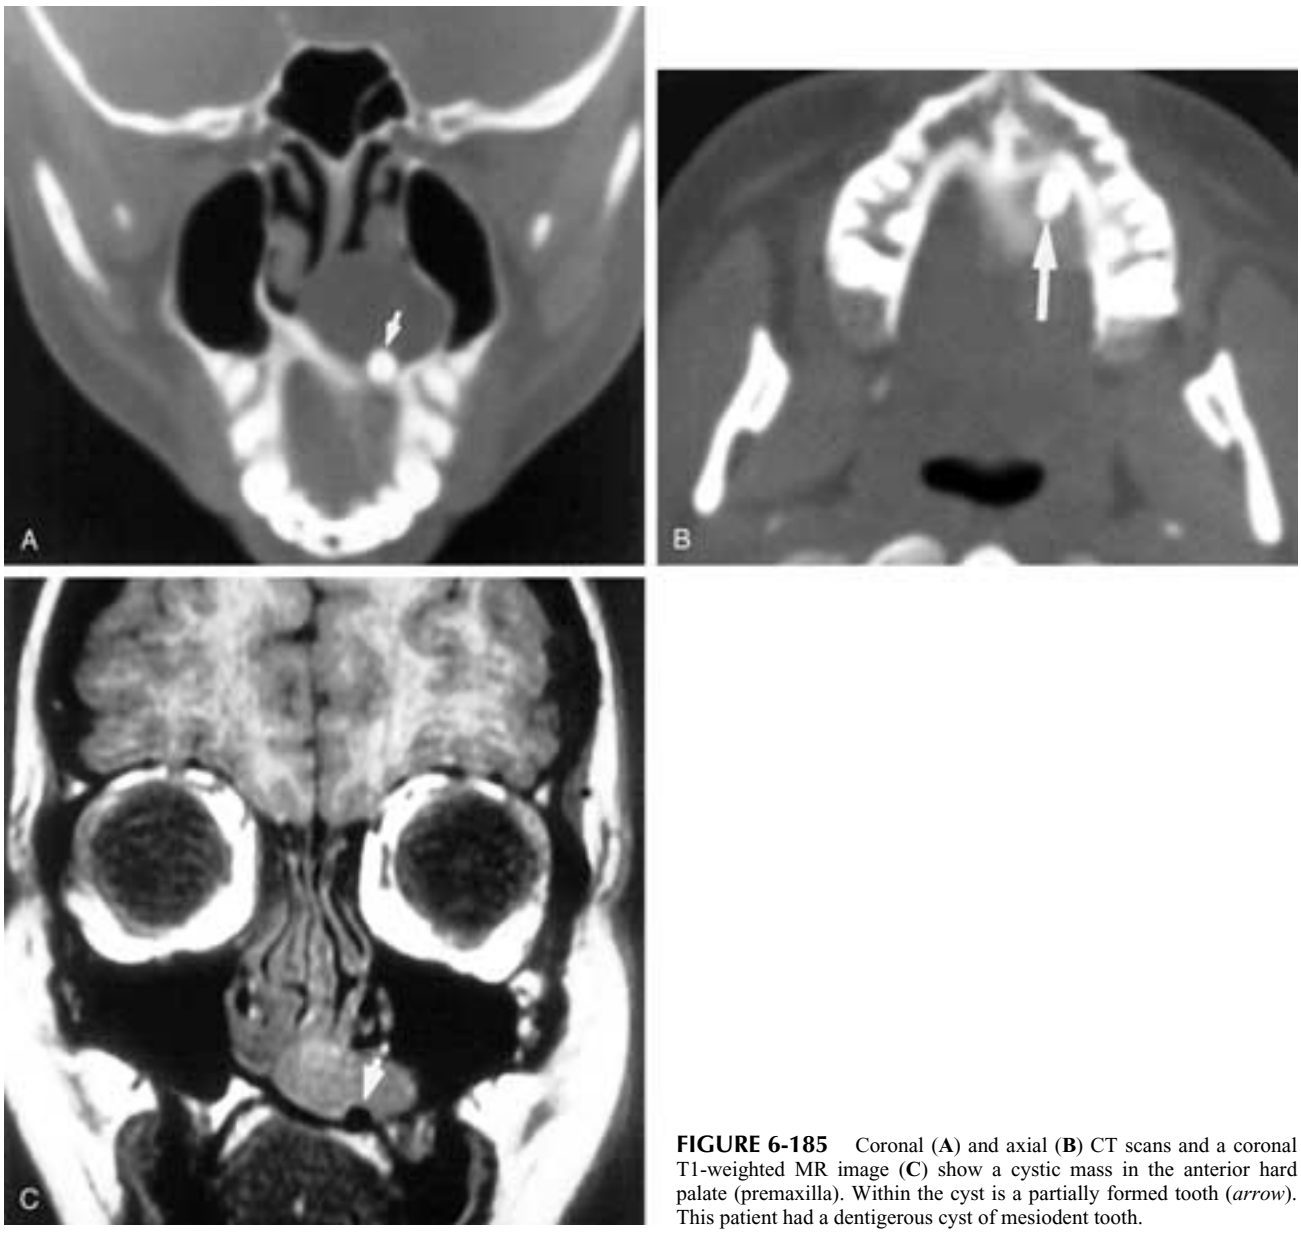

FIGURE 6-185 Coronal (**A**) and axial (**B**) CT scans and a coronal T1-weighted MR image (**C**) show a cystic mass in the anterior hard palate (premaxilla). Within the cyst is a partially formed tooth (*arrow*). This patient had a dentigerous cyst of mesiodent tooth.

The right orbital floor is also elevated. This patient had a dentigerous cyst.

VIEW IMAGE

whereas on T2-weighted studies they have variable intermediate and high signal intensities (Figs. 6-194 and 6-195).

Histologically, the epithelial component is characterized by basaloid cells forming ribbons or lining the perimeter of nests and islands. These islands can contain spindled cells mimicking (and thus called) stellate reticulum. The epithelial component can also contain squamous cells or granular cells. The latter contain lysosomal granules and may represent a degenerative phenomenon.[307] The stromal component of ameloblastoma contains mature fibroblastic and myofibroblastic elements.

The clinical course of ameloblastomas is characterized by slow, destructive growth without metastatic capacity. The tendency toward recurrence is dependent upon tumor site, stage, and primary therapy. A low recurrence rate (15%) can be seen after complete resection with negative margins.[307] Conversely, curettage or enucleation can be associated with a much greater likelihood of local tumor recurrence. Maxillary ameloblastomas are more likely to present with cortical destruction and invasion of soft tissues than mandibular tumors, and hence are inherently more likely to recur after resection. Skull base invasion and intracerebral extension can thus lead to death. There are two rare malignant variants of ameloblastoma: malignant ameloblastoma and ameloblastoma carcinoma. Malignant ameloblas-

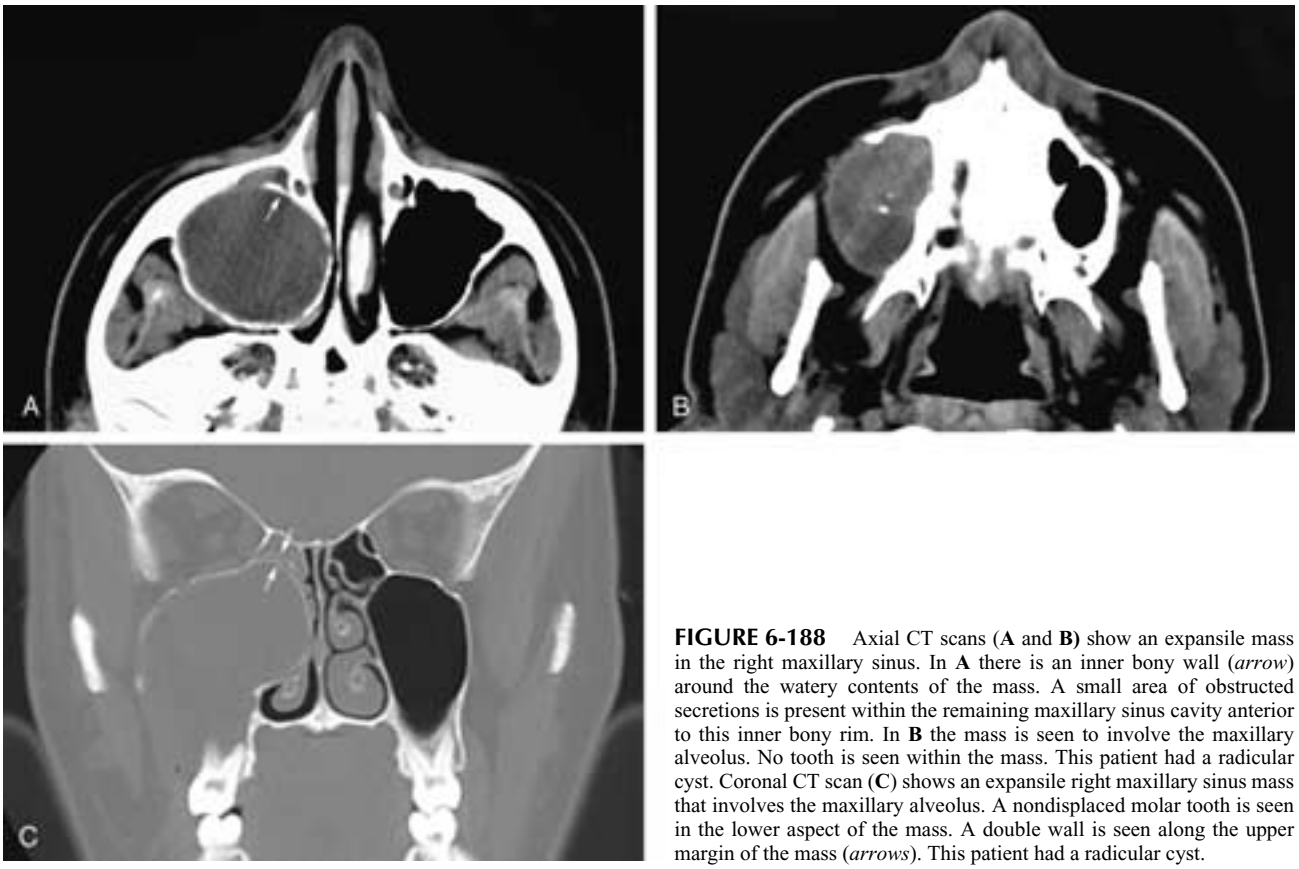

FIGURE 6-188 Axial CT scans (**A** and **B**) show an expansile mass in the right maxillary sinus. In **A** there is an inner bony wall (*arrow*) around the watery contents of the mass. A small area of obstructed secretions is present within the remaining maxillary sinus cavity anterior to this inner bony rim. In **B** the mass is seen to involve the maxillary alveolus. No tooth is seen within the mass. This patient had a radicular cyst. Coronal CT scan (**C**) shows an expansile right maxillary sinus mass that involves the maxillary alveolus. A nondisplaced molar tooth is seen in the lower aspect of the mass. A double wall is seen along the upper margin of the mass (*arrows*). This patient had a radicular cyst.

VIEW IMAGE

toma is histologically benign, yet it metastasizes. This usually occurs after a long history of multiple unsuccessful surgical procedures or after radiation therapy. Most metastases occur in the lungs, pleura, and regional lymph nodes.[312]

Ameloblastic carcinoma is histologically malignant, and the metastases are less differentiated than the primary tumor.

Complete surgical resection is the treatment of choice for all ameloblastomas. Chemotherapy appears to be relatively ineffective against both the primary lesion and the metastases, and most lesions are not radiosensitive.[312]

Unicystic ameloblastoma deserves special mention. It represents 5% to 15% of all intraosseous ameloblastomas and occurs almost exclusively in the mandible.[307] This lesion appears radiologically as a unilocular mandibular cyst.

Histologically, one sees a unilocular simple or plexiform cyst lined by ameloblastomatous tissue (as described above). Unicystic ameloblastomas may be treated more conservatively than typical ameloblastomas, by curettage or enucleation, with a low recurrence rate.

Cementoblastoma

Cementum-producing tumors can be classified as either benign cementoblastoma, gigantiform cementoma, periapical cemental dysplasia (previously discussed), and cemento-ossifying fibroma (previously discussed with fibroosseous jaw lesions). Cementoblastoma (also referred to as cementoma) is an uncommon neoplasm arising from the mesodermal periodontal ligament, which surrounds the tooth roots and contains cells able to produce cementum, bone, and fibrous tissue. Most patients are in their fourth decade of life or younger and present with a mandibular mass in the premolar-molar region. Because cementomas are attached to the tooth roots, tooth innervation can be disrupted and affected teeth can appear nonresponsive to vitality tests.[312]

Radiographically, these lesions appear as single or multiple well-defined radiopaque masses in continuity with the root apices of affected teeth. A zone of lucency, or ''halo,'' surrounds each lesion (Figs. 6-196 to 6-198). The radiographic differential diagnosis is primarily hypercementosis, which refers to the excessive accumulation of cementum along the surface of the involved tooth root(s). Hypercementosis is associated with Paget's disease, periapical inflammation, and elongation of a tooth as a result of the loss of its antagonistic opposing tooth.[312]

Histologically, cementum appears as coalescing trabeculae of eosinophilic matrix with basophilic reversal lines. Numerous active cementoblasts can be seen in cementoblastomas. These tumors have limited growth potential and are usually cured by local excision.

The gigantiform cementoma (familial multiple cementoma, cemento-osseous dysplasia) is a rare lesion characterized by single or multiple nodular, irregular masses ranging from 1 to 10 cm in one or both jaws. Only the alveolar processes are affected, independent of the teeth. Radiographically, one sees expansion of the cortical plates with concomitant simple bone cysts. Serum alkaline phosphatase is not elevated, thus excluding Paget's disease.

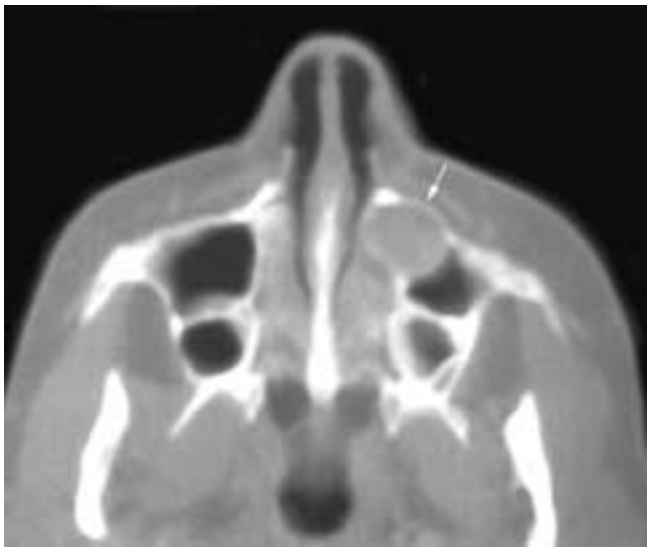

FIGURE 6-191 Axial CT scan shows an expansile soft-tissue mass (*arrow*) in the left anterior maxilla. The caudal aspect of the lesion extends down into the alveolus, separating the canine and lateral incisor teeth. This cyst has a thin rim of bone around its margin. This patient had a globulomaxillary cyst.

VIEW IMAGE

Histologically, one sees solid sheets of acellular cementum and some proliferative areas. Clinically, this is a self-limiting process, and treatment depends on the clinical course. Osteomyelitis is the most common complication.

VIEW IMAGE

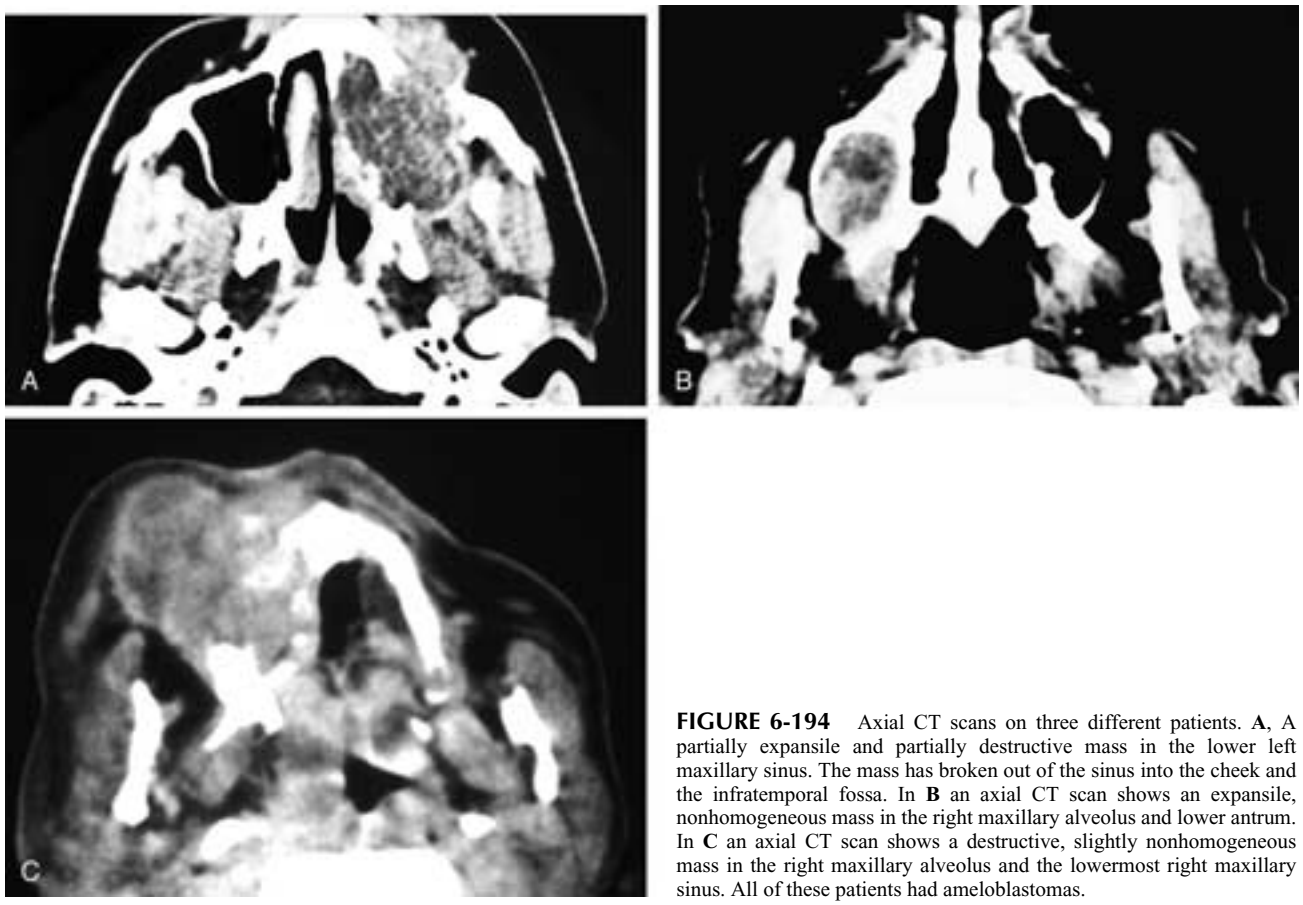
FIGURE 6-193 Axial CT scan (**A**) shows a soft-tissue density ovoid mass in the soft tissues of the right face deep to the lateral margin of the nose. The adjacent maxillary bone is uninvolved. In **B** a CT scan on another patient shows an ovoid mass in the lateral nostril region anterior to the medial maxilla. The bone is not involved. An incidental retention or polyp is present in the left antrum. Both of these patients had nasoalveolar cysts.

Odontoma

Odontomas are tumors that produce both the epithelial and mesenchymal components of the dental apparatus with complete, mature differentiation. Enamel, dentin, cementum, and pulp production can be seen within these tumors. These lesions usually occur within the second decade of life, affecting both genders equally; 59% occur in the maxilla.[307] Odontomas can be classified as either complex or compound; both occur with equal frequency. The complex odontoma has a haphazard arrangement of the elements. In compound odontomas the elements have a normal, more mature relationship to one another.[313]

Radiographically, the complex odontoma appears as an amorphous radiopacity. The compound odontoma has



VIEW IMAGE

FIGURE 6-194 Axial CT scans on three different patients. **A**, A partially expansile and partially destructive mass in the lower left maxillary sinus. The mass has broken out of the sinus into the cheek and the infratemporal fossa. In **B** an axial CT scan shows an expansile, nonhomogeneous mass in the right maxillary alveolus and lower antrum. In **C** an axial CT scan shows a destructive, slightly nonhomogeneous mass in the right maxillary alveolus and the lowermost right maxillary sinus. All of these patients had ameloblastomas.

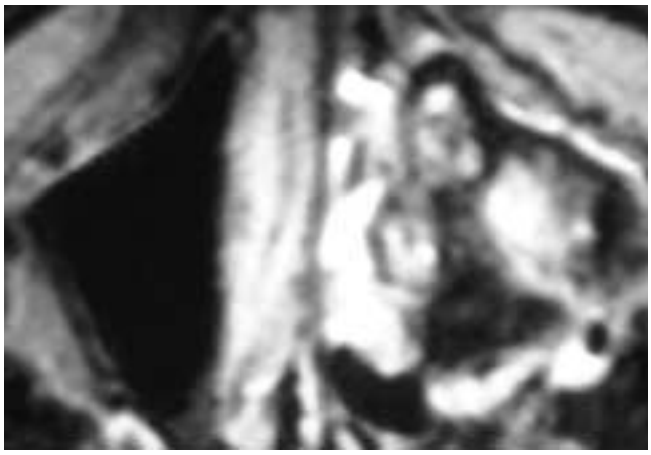

FIGURE 6-195 Axial T2-weighted MR image shows a nonhomogeneous mass in the left maxillary sinus. The lesion has extended into the nasal fossa and the infratemporal fossa. This patient had an ameloblastoma. The imaging appearance is similar to that of a minor salivary gland tumor in this sinus.

anywhere from 3 to 2000 miniature teeth (or denticles), with single roots or no roots (Figs. 6-199 through 6-201). All odontomas are surrounded by a thin, radiolucent halo that represents the fibrous capsule. Radiographically, the differential diagnosis includes prior bone grafting.

Bone grafting to the maxillary floor can be performed for patients who require dental implants but have insufficient native bone to support them (Fig. 6-202). This imaging appearance should not be confused with that of an odontogenic tumor.

FIGURE 6-196 Intraoral occlusal film shows a calcified palatal mass with a surrounding lucent zone (*arrows*). Note the small radiopaque densities surrounding the tooth roots (hypercementosis). This patient had a cementoma.

FIGURE 6-197 Lateral view shows a calcified mass with a surrounding lucent zone in the maxillary alveolus and in the mandible. This patient had two cementomas.

Histologically, complex odontomas contain a disorganized array of dentin, cementum, enamel, and tooth pulp. In compound odontomas, one sees actual attempts at tooth formation. Treatment involves complete surgical excision; recurrences are rare.

Calcifying Epithelial Odontogenic Tumor

The calcifying epithelial odontogenic tumor (Pindborg tumor) is a benign odontogenic neoplasm that constitutes

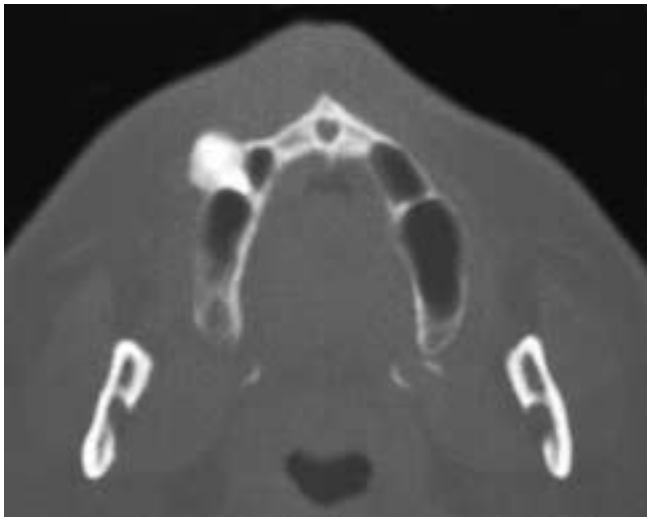

FIGURE 6-198 Axial CT scan shows a dense osseous mass arising in the right maxillary alveolus. The lesion is localized to one area, and the remaining alveolus is normal. This patient had a cementoma.

VIEW IMAGE

FIGURE 6-199 Lateral view shows a large, expansile mass in the left maxillary alveolus and antrum. There are innumerable discrete, toothlike densities (denticles). This patient had a compound odontoma.

1% of this class of tumors. It usually occurs in patients in the fourth and fifth decades of life, although it has been reported in patients with an age range of 2 to 82 years.[307] These tumors are equally divided between males and females and occur twice as often in the mandible as in the maxilla. Most often the premolar teeth are affected. Although most tumors are asymptomatic and are discovered incidentally on dental radiographs, they also may cause jaw expansion. Between 35% and 45% of cases are associated with an impacted tooth.[307]

Pathologically, there are sheets of polyhedral or spindle cells, with sharply defined borders and prominent nuclei. The ultrastructure of the spindle cells has characteristics of myoepithelial cells. A capsule is variably present. Calcospherites composed of apatite crystals form laminations (Liesegang's rings) throughout the tumor. A variation of the tumor is a clear cell type, whose cells contain glycogen.[307]

Radiographically, most of these tumors are initially radiolucent, multilocular lesions with indistinct margins. The calcifications generally appear later and may be extensive or may not be seen on plain films, being too small. On CT and MR imaging these tumors are usually partially expansile, bulky maxillary sinus lesions with areas of calcification (Fig. 6-203). The differential diagnosis includes ameloblastoma, odontogenic myxoma, central GCG, follicular cyst, and OKC.

Metastatic renal cell carcinoma may at first be included in the differential diagnosis when there is a prominent clear cell population, but the presence of sheets of epidermoid-appearing cells in the Pindborg tumor helps eliminate this possibility.[307] A malignant variant with the capacity for metastasis has been described. This tumor revealed marked nuclear and cellular hyperchromatism, giant cells, and abnormal mitoses.[307]

Treatment of the Pindborg tumor varies from curettage for small lesions to en bloc resection for larger lesions. If not completely removed, these tumors will recur.

HAMARTOMAS, TERATOMAS, AND TERATOCARCINOMAS

The term *hamartoma* refers to an abnormal, oncologically benign proliferation of indigenous tissues. The sinonasal tract is the most common site for head and neck hamartomas, usually in the area of the nasal septum. Histologically, one sees benign disorganized epithelium, salivary glands, muscle, and cartilaginous and vascular tissues.[314, 315]

An epithelial variant, respiratory epithelial adenomatoid hamartoma, has been reported. Clinically, these neoplasms appear similar to inflammatory polyps, but are more

FIGURE 6-201 Coronal CT scan (**A**) shows a very dense nodular mass in the right maxillary alveolus. Axial CT scan (**B**) on another patient shows a mass in the right maxillary sinus with numerous discrete radiodensities. Obstructed secretions are present laterally in the sinus. Both of these patients had a complex odontoma.

indurated and occur at sites atypical for inflammatory polyps (posterior nasal septum). These differ from conventional sinonasal hamartomas in that there is a prominent glandular proliferation mimicking inverted Schneiderian papillomas or intestinal-type adenocarcinomas.

The term *teratoma* refers to a neoplasm-producing tissue that recapitulates all three germ layers (ectodermal, mesodermal, and endodermal). Teratomas may be histologically mature and oncologically benign, such as a dermoid cyst. A ''hairy polyp'' is essentially a polypoid, epithelium-lined dermoid of the nasopharynx that is seen in the pediatric population. It may be considered a benign teratoma; however, others believe it to be choristomatous since, unlike dermoids, it has limited growth potential.[316] Teratomas may also be histologically immature while being oncologically benign, or they may harbor malignant components and have aggressive biologic potential. As a general rule, pediatric head and neck teratomas tend to be oncologically benign, whereas adult teratomas tend to be histologically and thus oncologically malignant.[317] An epignathus, or ''fetus-in-fetus'' (unequal conjoined twins in which the smaller, incomplete one [the parasite] is attached to the larger twin [the autosite] at the jaw), is an extreme example of a neonatal teratoma originating from the jaw and presenting as a massive, protruding oral neoplasm. Other neonatal teratomas can originate from the soft tissues of the thyroid and cervical region. While these tumors are grotesquely manifest and can cause fatal upper airway obstruction, they are usually oncologically benign. Thus, prenatal surgical intervention can convert an otherwise moribund situation. Sinonasal teratomas (teratocarcinoma, malignant teratoma, teratocarcinosarcoma) have been reported predominantly in the adult population, with a male predominance.[314] The presenting symptoms are those associated with a sinonasal mass. Radiographically and grossly, these tumors are heterogeneous, with solid and cystic components. Histologically, one sees a mixture of immature, benign teratomatous tissue (e.g., epithelial, mesenchymal, differentiated cartilaginous) and a histologically malignant component that is usually carcinomatous but may be of any derivation. Sinonasal teratomas are associated with a high mortality rate, despite multimodality treatment.

METASTATIC DISEASE TO THE SINONASAL CAVITIES

Metastasis from primary tumors below the clavicles to the sinonasal cavities is infrequent. Only about 100 have been reported, the most common of which is metastatic renal cell carcinoma (RCC). Tumors found in the sinonasal cavities precede the diagnosis of the primary tumor in 8% of patients.[13] Next in frequency are tumors of the lung and breast; these are followed considerably less frequently by tumors of the testis, prostate, and gastrointestinal tract.[13, 318, 319] Soft-tissue sinonasal metastasis from esophageal carcinoma, initially mimicking acute sinusitis, has been rarely reported.[320]

The average age of patients with metastatic renal cell tumors to the sinonasal cavities is the sixth decade of life,

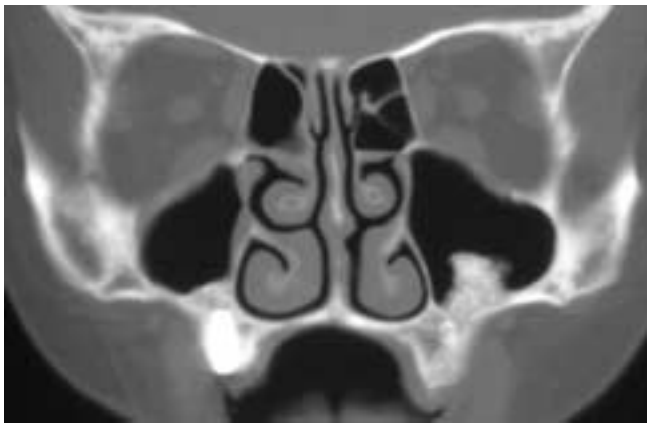

FIGURE 6-202 Coronal CT scan shows a dental implant in the right maxillary alveolus. In the floor of the left antrum, there is a bony prominence that represents transplanted bone placed to support a future left-sided dental implant.

similar to that of patients with breast carcinoma metastases. Bronchogenic and gastrointestinal tract metastases generally appear in the fifth decade of life.

Symptoms of metastases are nonspecific, except for the renal cell lesions, which commonly cause epistaxis.[321] Generally, metastatic neoplasia to the sinonasal tract is associated with a poor prognosis. However, isolated metastatic RCC to the sinonasal tract, in the absence of disease dissemination, may be associated with a good survival after resection.[322, 323]

We have recently seen a patient with histologically confirmed metastatic RCC to the sinonasal tract in the radiologic absence of a primary renal neoplasm. This metastasis presumably occurs with a regressed primary RCC, since spontaneous regression of primary or metastatic RCC can occur as a rare phenomenon (Fig. 6-204).[324, 325]

Squamous and basal cell carcinomas of facial and scalp skin may metastasize to the central skull base, usually along neurogenic pathways. These metastases can occur despite negative specimen margins of the resected primary skin tumor. In these cases, the most accurate prognostic finding is perineural tumor invasion in the primary lesion.[326–328] In rare instances, skin melanomas metastasize to the sinonasal cavities. Along with the metastases from RCCs, these lesions are the most vascular metastases and often manifest with epistaxis.

Thyroid carcinoma metastatic to the paranasal sinuses is rare.[329–334] The patient may have symptoms related to the distant metastasis rather than the primary tumor. Such metastases in differentiated thyroid carcinoma portend a poor prognosis.

A case of an endometrial carcinoma metastatic to the paranasal sinuses has also been reported, as has a rare case of metastatic choriocarcinoma to the nasal cavity from testicular teratoma in a patient who presented with intractable epistaxis.[335, 336]

On CT, metastases from lung, breast, distal genitourinary tract, and gastrointestinal tract tumors are aggressive, bone-destroying soft-tissue masses that enhance minimally, if at all. The metastases are usually indistinguishable from a primary sinonasal SCC. By comparison, metastases from primary RCCs and melanomas are enhancing masses that may remodel the sinonasal walls as well as destroy them. Prostate carcinoma is one of the few primary tumors that may give a purely blastic metastasis to the facial bones and skull. Although a

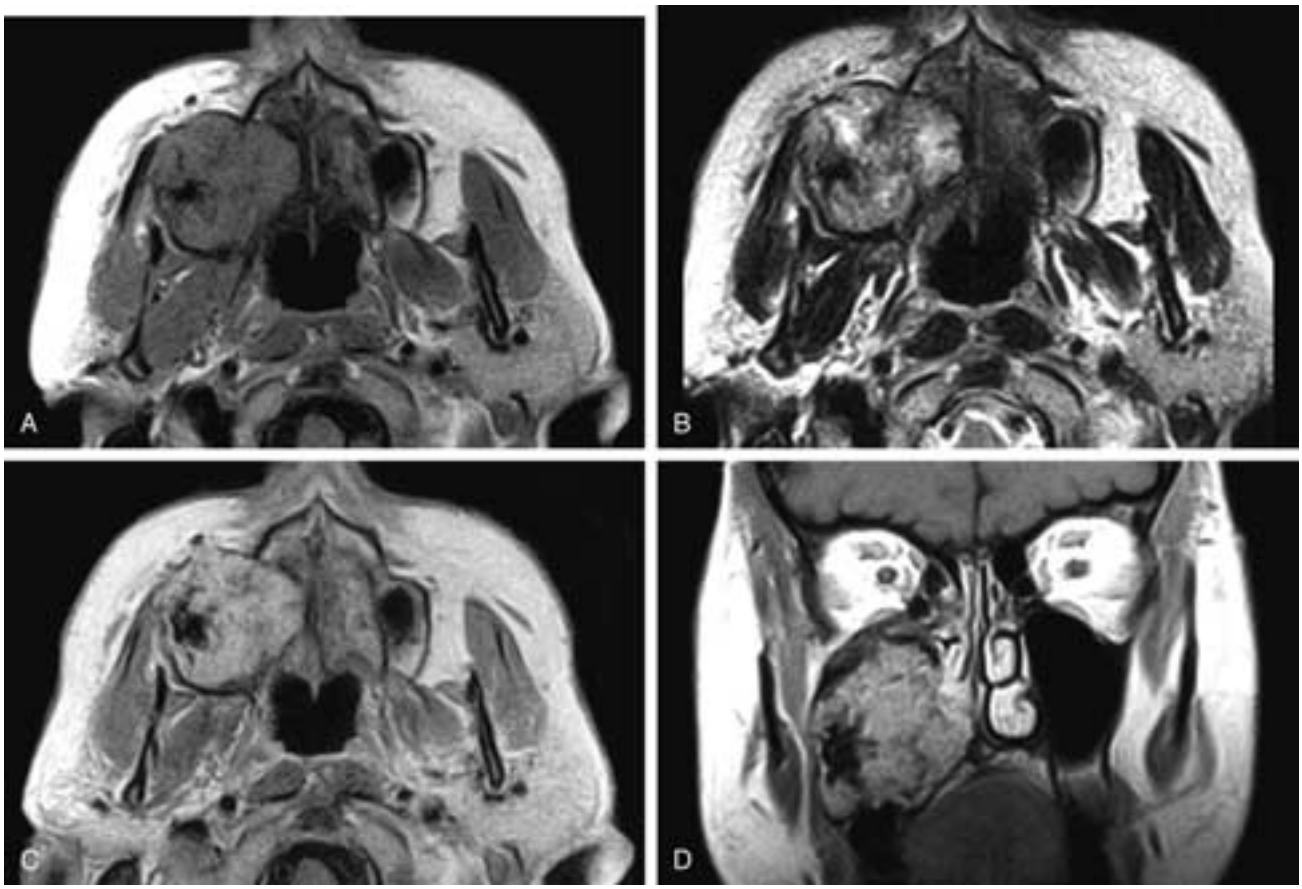

FIGURE 6-203 Axial T1-weighted (**A**), T2-weighted (**B**), and axial (**C**) and coronal (**D**) T1-weighted, contrast-enhanced MR images show a soft tissue mass in the right maxillary sinus with a low T1-weighted signal intensity and a nonhomogeneous T2-weighted signal intensity. The mass enhances slightly. There are areas of signal void within the lower lateral aspect of the mass on all sequences that were calcifications. This patient had a calcifying epithelial odontogenic tumor.

VIEW IMAGE

FIGURE 6-204 Coronal T1-weighted (**A**), T2-weighted (**B**), and T1-weighted, fat-suppressed, contrast-enhanced (**C**) MR images and an axial CT scan (**D**) show a spherical noninvasive mass in the upper left nasal fossa. The mass obstructs the remaining left ethmoid cells and the left maxillary sinus. The mass has a low T1- and T2-weighted signal intensity, and it enhances. The spherical shape suggests that this is either a minor salivary gland tumor or a lesion such as a schwannoma. This was a clear cell tumor metastatic from renal cell carcinoma.

VIEW IMAGE

soft-tissue mass may occur, often only a sclerotic, slightly thickened bone with an abnormal, irregular trabecular pattern is seen. On CT this pure bone disease can be overlooked unless wide windows are used to evaluate the bone.

The most important radiographic indication of metastasis is the presence of more than one lesion, particularly because sinonasal tumors usually do not erode multiple areas of bone. Rather, contiguous sites of bone erosion spread from an area of initial involvement. Thus, two areas of bone erosion with intervening normal bone suggest metastatic disease. However, a solitary destructive lesion may always represent a metastasis and the imaging appearance is nonspecific, often overlapping with that of other lesions that arise within the central skull base and sella (Figs. 6-205 to 6-214).

FIGURE 6-206 Axial contrast-enhanced CT scan shows an enhancing mass in the left ethmoid sinuses and nasal cavity and a second mass in the occipital horn. This patient had metastatic melanoma.

SECTION ONE

FACIAL FRACTURES

INTRODUCTION

The paranasal sinuses develop within and are protected by the facial bones. The facial bones also surround and protect the orbits, nasal fossae, and mouth, they support the maxillary dentition, and they serve as attachments for the facial muscles. The facial skeleton can be considered as a honeycombed structure of varying thickness and form that develops strength along stress zones by forming buttressed arches. In general, the most superficial portion of the facial skeleton is physically the strongest and serves the additional function of protecting the more delicate central part of the face. The honeycombed construction of the middle third of the facial skeleton evolved to resist the vertical masticatory forces, and in this regard it provides excellent stability. However, external impact forces directed toward the midface can disrupt this central structure, and the fracture of even one buttress can weaken the entire lattice, causing it to

Copyright © 2003, Mosby, Inc. All rights reserved.

collapse. Fortunately, such collapse is often prevented by the strength of these same facial buttresses and the additional support of the skull base.[1, 2]

FACIAL BUTTRESSES

The facial skeleton can be analyzed in terms of the supporting buttresses that comprise its structure. There are two main sagittal buttresses on either side of the face. There is a medial buttress that extends from the anterior maxillary alveolus up the lateral wall of the pyriform aperture, which is the opening in the facial skeleton that defines the margins of the nasal fossae, and into the medial orbital wall. This nasomaxillary buttress is thus formed by the lower maxilla, the frontal process of the maxilla, the lacrimal bone, and the nasal process of the frontal bone. There is also a lateral buttress, the zygomaticomaxillary buttress, which is formed on either side by the lateral wall of the maxilla, the body of the zygoma, and the orbital process of the frontal bone in the lateral orbital wall. A third buttress has been suggested, the pterygomaxillary buttress, which extends from the posterior maxillary alveolus (tuberosity) cranially along the pterygoid plates to the skull base.

These buttresses have evolved as mechanical adaptations of the skull to masticatory forces, and the greatest occlusal forces are absorbed by the zygomaticomaxillary buttress, as evidenced by the thick cortical bone present in the lateral maxillary-zygomatic region when compared with the more fragile medial maxillary wall. In addition to these sagittal buttresses, some authors believe that there is also a median buttress formed by the nasal septum. Overall these craniocaudal buttresses are curved, and analysis suggests that they need reinforcement by axial struts. Thus these sagittal buttresses are interconnected by three axial (horizontal) struts that are formed by the floor of the anterior cranial fossa, the orbital floor and zygomatic arches, and the maxillary alveolus and hard palate. In addition, the skull base, which is oriented at approximately a 45° angle to the occlusal plane of the maxilla, acts as an additional axial buttress. Together these buttresses or struts form an interconnecting facial support system.

The facial skeleton can also be conceptualized as being formed by two coronal buttresses: an anterior plane formed by the vertical portion of the frontal bone (glabellar region), the orbital rims, the anterior maxilla, and the alveolus; and a posterior plane formed by the posterior wall of the maxilla and the pterygoid processes.[1, 3, 4]

Such analyses, first studied experimentally by Le Fort, have led to an understanding of the major lines of weakness in the midfacial skeleton, and these, in turn, have helped explain why certain fractures follow an overall predictable course. The efforts of Le Fort are recognized today by the Le Fort types I, II, and III fractures. The forces he used experimentally are similar to the low-velocity impact forces that occur today in fist fights and sporting events. However, at present there are also high-velocity impact injuries such as those that occur in high-speed vehicular accidents and with violence involving blunt devices or gunshot wounds. Despite the much greater order of magnitude of these impact forces, the same fracture lines are still encountered, albeit in various combinations other than those originally observed by Le Fort.[1, 2]

In addition to causing complicated facial fractures, such high-impact trauma rarely may be associated with cervical spine injury. In one study of 582 consecutive patients with facial fractures, 1.04% (6) were found to have a cervical spine injury, all of which were the result of a car accident.[5] Thus, the proper workup of a patient with severe facial fractures should also include evaluation of the cervical spine. In addition, imaging of these patients should include the brain and the carotid arteries for associated trauma.

CLINICAL DIAGNOSIS AND TREATMENT

The diagnosis of facial fractures usually is accomplished by a combination of clinical and imaging examinations. The clinician is primarily concerned with the detection of malocclusion, abnormal mobility, and crepitation as signs of fracture. Often, deformity of the facial skeleton is initially concealed by overlying edema, hemorrhage, and soft-tissue injury. Any evidence of a palpable step-off at the orbital rim, diplopia, hypertelorism, midfacial elongation, cerebrospinal fluid (CSF) rhinorrhea, or flattening of the cheek further helps the clinician identify the type of fracture present. However, only after imaging studies can the fractures be completely identified and characterized. It is now recognized that the information gained from CT scans is of greater net value than that gained from a combination of routine radiographs and clinical examination. Thus imaging is essential for proper treatment planning in these cases.[1, 2, 6]

In many instances, clinicians wait several days after the trauma before reducing the fracture(s). This delay allows some of the soft-tissue injury to subside and may be necessary if the patient has other life-threatening injuries that require immediate attention (before the less critical facial fractures are addressed). However, if possible, a delay of more than 7 days is to be avoided, because after this time fibrous fixation of the fracture occurs and fracture reduction becomes more difficult, often requiring refracturing to attain normal positioning.

The basic principles of treating midfacial fractures are (1) reduction of the fractures and (2) fixation of the fractured bones to one another and to the skull. Absolute immobilization of the fractures is the main prerequisite for rapid and undisturbed healing because the main interferences with fracture healing are local mechanical factors. In the early phase of fracture healing, mobility can disturb the normal course of bone regeneration and lead to faulty differentiation of the callus.[1, 2, 7–9] Of primary clinical concern is the restoration of occlusion and facial form, because these provide a means of restoring the essential masticatory function. Midfacial restoration is accomplished by means of arch bars applied to the maxillary and mandibular teeth and then, after manipulation is held in good occlusion, by fixing the arch bars together with small rubber bands. Such fixation of the midface must be maintained until bony union and consolidation are achieved. If internal wire fixation is used, immobilization usually takes 6 to 8 weeks. Intermaxillary fixation alone requires 3 to 4 weeks to prevent further occlusal malalignment.[8, 9] However, today most internal fixation is accomplished by the use of microplates or

Copyright © 2003, Mosby, Inc. All rights reserved.

miniplates and screws (Fig. 7-1).[8–10] With this technique, intermaxillary fixation is accomplished without a waiting interval. In addition, the growing use of microplate fixation has almost made obsolete the complex internal fixation schemes accomplished with wire sutures and wire suspensions (Fig. 7-2). External fixation for facial fractures using a halo frame with fixation bars is also less common due to the utilization of microplates.

Infections of the fracture line are among the most serious complications of facial fractures. Any fracture must be considered potentially infected if it traverses the alveolus, the walls of the nasal skeleton, or the paranasal sinuses or communicates with a soft-tissue wound. Such fractures are called *compound fractures,* and appropriate antibiotic therapy reduces the chances of infection in these fractures.[1, 2, 8, 9] With good treatment the risk of infection of a maxillary or midfacial fracture is only about 2%, and the risk of osteomyelitis is 0.5%. However, a treatment delay of 2 to 3 weeks raises the incidence of osteomyelitis to 1.3%.[8, 9] Similarly, posttraumatic sinusitis occurs in 7.25% to 9% of all the patients with midfacial fractures, and proper maintenance of sinus drainage must be a therapeutic consideration.[7]

It is not uncommon to encounter multiple bone fragments during open reduction of facial bone fractures. When these fragments are few and their size is large, there is no problem. However, multiple small, thin bone fragments are difficult to handle, making accurate reduction with interfragmentary wires problematic. This is frequently encountered in fractures of the anterior maxillary wall, orbital floor, orbital roof, and frontal sinus. Therefore, many surgeons reconstruct the larger segments and discard the smaller segments. In one study, 10 patients who sustained facial fractures with multiple small, thin fragments were treated with tissue adhesive (*n*-butyl-2-cyanoacrylate). Postoperative three-dimensional (3D) CT scans demonstrated excellent reconstruction following this technique.[11]

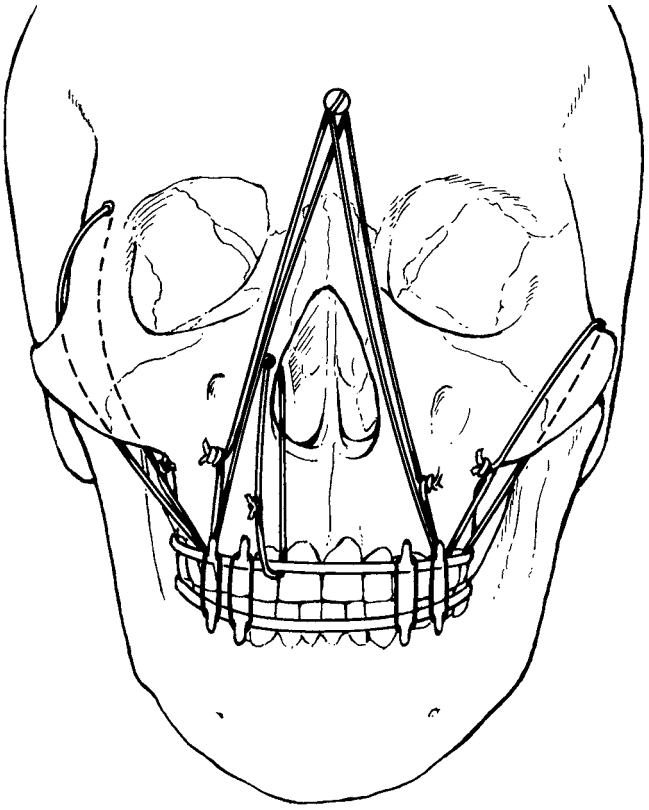

FIGURE 7-2 Frontal diagram of the different types of intraosseous wiring. The maxillary and mandibular teeth are fitted with arch bars, which are held together with rubber bands. With the patient in good occlusion, fixation can be achieved by frontomalar suspension, glabella (screw) suspension, pyriform aperture suspension, or circumzygomatic suspension.

VIEW IMAGE

Thus, the concepts of treating craniomaxillofacial fractures have changed over the last 15 years, and modern imaging techniques play a central part in establishing a proper diagnosis. In addition, advanced life support and intensive care medicine now allow for early primary fracture treatment. The former principles of minimal exposure of bone fragments using small incisions have been replaced by principles from reconstructive craniofacial surgery comprising extensive subperiosteal dissection, exposure of all fracture lines, open reduction, and rigid internal fixation. Missing bony structures are replaced primarily by autogenous bone grafts or the use of exogenous materials. By using these concepts, most late esthetic and functional sequelae of facial fractures can be dramatically reduced.[12]

The final goal in reconstructing the facial skeleton of trauma patients is to obtain good cosmetic and functional outcomes. To accomplish those goals, many surgeons believe that the key to repairing midfacial fractures is the correct placement of the zygomatic arch in relation to the cranial base and the midface. In this way the transverse,

vertical, and sagittal diameters are regained in their correct spacial relationships.[13]

IMAGING

CT is the modality of choice for the most complete evaluation of the facial skeleton and facial soft tissues.[14] Although contrast-enhanced CT scans can assess the brain and dural spaces, which so often have associated damage in the severe accidents that cause facial trauma, these structures are better evaluated with MR imaging.[15] The most useful diagnostic information is gained by utilizing both axial and coronal CT scans.[16, 17] That is, a single-plane CT study does not provide as detailed information as an orthogonal two-plane examination. Specialized sagittal or oblique plane studies, although helpful in specific cases, are generally considered optional.[8] These specialized reconstructions usually appear degraded when compared to the original acquisition plane images; however, with the use of multidetector CT units, such deficiency may be a thing of the past.

Helical CT provides a means of obtaining better-quality two-dimensional (2D) reconstructions in any plane and provides excellent 3D reconstructions. Although some detail is lost as part of the smoothing algorithm, the 3D images serve as an excellent communication tool with the surgeons.[18, 19] These 3D images usually allow clinicians to visualize the fracture segments and their relationship to one another better than on a series of 2D scans in any one plane. Although these 3D images have been shown to be of little value in the temporal bone, they have considerable value in the skull base and the facial skeleton, especially if surfaces are involved or fragments are displaced.[20] With the newer 3D software, the fracture segments can be manipulated on screen so that the clinician can evaluate a particular treatment approach or the results of a treatment plan. In addition, 3D models can now be constructed from the CT data, allowing hands-on preoperative planning in complex cases.[18] It has been shown that measurement of the skull and facial bone landmarks by 3D reconstruction is quantitatively accurate for surgical planning and treatment evaluation of craniofacial fractures.[21]

Because MR imaging does not visualize the bone directly, small yet unstable nondisplaced facial fractures may not be seen. Although MR imaging can be helpful in differentiating blood from inflammatory reactions and edema fluid, such a distinction is rarely of clinical importance. By 48 hours after the trauma, intrasinus blood has a high methemoglobin content. If MR imaging is performed at this time, the blood has a high T1-weighted signal intensity, while edema and infection have intermediate to low T1-weighted signal intensities.[22]

In addition to evaluating the facial bones, the skull base also must be carefully examined, as fractures of the anterior cranial fossa are found in 7.1% of central midfacial fractures, 14.7% of centrolateral midfacial fractures, and 1.1% of lateral midfacial fractures.[7] The midfacial area is formed by the paired maxillae, palatal bones, inferior turbinates, lacrimal bones, nasal bones, zygomas, and solitary vomer and ethmoid bones. Central midfacial fractures include all forms of fractures that occur between the root of the nose and the alveolar processes of the maxillae, without involvement of the zygomas. These fractures include the alveolar process fracture of the maxilla, with detachment of teeth; the transverse fracture just above the floor of the nasal cavity, with separation of the palate and alveolus (Le Fort I, or Guérin's, fracture); the median or paramedian sagittal fracture of the hard palate; the pyramidal fracture, with separation of the midface either with the nasal bones (Le Fort II and Wassmund II) or without the nasal bones (Wassmund I); and fractures of the nasal bones and the nasoethmoidal region.[7]

Lastly, it must be remembered that with minor trauma, no fracture may be present and yet there are reportable findings. Thus, intrasinus hemorrhage, subcutaneous edema, subcutaneous hematomas, and foreign bodies may be present (Fig. 7-3). These findings must be noted, as they serve to explain

facial deformity and epistaxis that may clinically suggest a fracture.

NASAL FRACTURES

Nasal injuries are the most common fractures of the facial skeleton; about 50% of facial fractures are isolated fractures of the nasal pyramid.[10, 14] That is, nasal fractures can occur either as isolated fractures or in association with other facial injuries. A distinction should be made between fractures of the cartilaginous nasal structures and those of the nasal bones because they represent different types of injuries.[1, 2]

The extent of disruption of the nasal structure relates to the direction and degree of the force causing the injury (Fig. 7-4). The lateral impact injury is more common than the frontal injury; 66% of nasal fractures result from a lateral force, but only 13% are the result of a frontal impact.[23] Although not universally used, one of the main classification systems for nasal bone fractures divides the frontal injuries into three types. In plane 1 injuries, the injury does not extend dorsal to a plane that extends from the caudal tip of the nasal bones to the anterior nasal spine. The majority of the impact is absorbed by the lower nasal cartilages and the nasal tip. Separation and avulsion of the upper lateral nasal cartilages occur, and occasionally there is posterior dislocation of the septal and alar cartilages. In plane 2 injuries, the external nose, the nasal septum, and the anterior nasal spine are all involved. There is splaying or flattening of the nasal bones; septal cartilage tears and overriding may occur. In plane 3 injuries, the orbital and possibly the intracranial structures are also involved. Typically there are comminuted nasal bone fractures, and fractures of the frontal processes of the maxillae, the lacrimal bones, and the ethmoid labyrinth. Severe nasal septal injuries can result in upward extension that may involve the cribriform plate and orbital roof.[23]

With weak lateral (oblique) impacts, plane 1 injuries result and involve only the ipsilateral nasal bone. Typically the lower nasal bone, the frontal process of the maxilla, and possibly the pyriform aperture margin are medially displaced. Lateral plane 2 injuries result from a greater force than plane 1 injuries. The fracture results in medial displacement of the ipsilateral nasal bone and lateral displacement of the contralateral nasal bone and nasal septum. Lateral plane 3 injuries are still more severe and result in nasal bone fractures with involvement of the nasal septum, the frontal process of the maxilla, and the lacrimal bone.[23]

In summary, the majority of nasal bone fractures involve the thinner, distal third of the nasal bones, and the nasoethmoid margin remains intact.[1, 2, 10] A lateral blow to

Copyright © 2003, Mosby, Inc. All rights reserved.

the nose usually causes a simple cartilage depression or fracture of only the ipsilateral nasal bone (Fig. 7-5). However, an anteriorly placed nasal blow usually fractures both nasal bones at their lower ends, and because the force is absorbed by the nasal septum, the septum is also displaced and fractured.

With a greater force, the entire nasal pyramid, including the frontal processes of the maxillae, may become detached (Fig. 7-6).[10] When the nasal bones and septum are displaced posteriorly, a saddle nose deformity and splaying of the nose result.[1, 2] In more severe fractures, traumatic hypertelorism and telecanthus may occur, and hemorrhage caused by rupture of the anterior or posterior ethmoidal arteries may be severe.

In adults, the internasal suture is solidly ossified so that the nasal bones function as a unit between the frontal processes of the maxilla. However, in children the internasal suture is not yet ossified, and the nasal bones are essentially hinged on each other while resting on the frontal processes of the maxillae. As a result, the frontal processes usually are

not fractured in childhood nasal injuries.[1, 2] In fact, it has been noted that in children there is a less prominent nasal projection (the nasal bone length is almost equal to the width), and there is increased elasticity and stability of the midface due to the presence of developing bone, the relative lack of sinus pneumatization, and the state of mixed dentition. There is also increased shielding of the facial skeletal structure due to the disproportionate amount of soft tissue relative to bone, and the small weight and size of the child decrease inertial impact forces.[23]

If the nose is struck from the side and near its base, the lateral cartilaginous walls may be displaced, and this type of injury is not identified radiographically. Further, edema and hemorrhage usually fill in the resulting surface depression and obscure clinical detection of the deformity. If these injuries and simple nasal fractures initially go undetected, especially if they occur in conjunction with more serious injuries, the inadequately treated nasal trauma may result in cosmetic deformity and functional impairment.[1, 2]

If the nasal trauma results in buckling of the nasal septal cartilage, the fractured cartilage fragments may overlap one another, thereby separating the perichondrium from the cartilage. This event allows a hematoma to develop in the space between the perichondrium and the cartilage, and this hematoma interferes with the cartilage's overlying mucoperiosteal vascular supply. Eventual cartilage necrosis occurs. If such a septal hematoma is not initially identified and treated, it becomes an organized hematoma that causes a firm, unyielding thickening of the septum and impaired breathing.

If a septal hematoma becomes infected after mucosal injury, a septal abscess develops, with fever, pain, septal swelling, eventual cartilage necrosis and resulting loss of nasal support and the development of a saddle nose deformity, and possible intracranial spread of the infection.[1, 2] To avoid these complications, it is essential to have careful clinical examination of the nasal septum and early evacuation of a septal hematoma. If imaging studies of the nose and nasal fossae are also performed, the radiologist should always direct attention to the nasal septum to identify any localized septal swelling or traumatic deviation (septal bone fracture and/or cartilage dislocation).[1, 2]

One study demonstrated that, based on clinical examination, 25% of patients required surgical reduction of a nasal fracture or dislocation despite a negative plain film examination.[24] In addition, there is a poor correlation (6.6% to 10%) between the plain film demonstration of a fracture and the need for surgical reduction.[23] In more severe injuries, a higher detection rate and better clinical correlation are achieved with the use of CT. Actual fracture of

Copyright © 2003, Mosby, Inc. All rights reserved.

cartilage may not be imaged by any modality. However, in these cases, cartilage dislocation or a focal hematoma usually draws attention to the injury.

CENTRAL MIDFACIAL FRACTURES

Nasoorbital Fractures

The nasoorbital fracture most often results from a blow over the bridge of the nose. The force displaces the nasal pyramid posteriorly, fracturing the nasal bones, frontal processes of the maxillae, lacrimal bones, ethmoid sinuses, walls of the frontal sinuses, cribriform plate, and nasal septum. The ethmoid lamina usually fractures on itself in an accordion fashion, and this is best visualized on CT in the axial plane. Posttraumatic hypertelorism and telecanthus may result, as well as associated damage to the lacrimal apparatus and the medial canthal tendon (Fig. 7-7). Careful attention also should be given to any fractures involving the bones near the optic canal, as a surgical attempt to reduce the facial bone fractures may displace such an optic canal fracture and cause blindness.

In the floor of the anterior cranial fossa the dura is thin and firmly adherent to the bone. Thus the skull base and dura in the anterior cranial fossa function as a unit, and a fracture through this region invariably tears the dura. Dural tears provide a pathway for CSF rhinorrhea and the development of an intracranial pneumocele or infection (Fig. 7-8).[1, 2] In one series, motor vehicle accidents accounted for nearly 70% of these cases, and 63% of the patients had associated severe nonfacial injuries. In addition, 51% of the cases had central nervous system injury and 42% of the patients had CSF leakage. Telecanthus was present in 12% of the cases.[25, 26] Thus, if a fracture in the region of the nasion is identified on imaging, a careful search should always be made for any associated intracranial traumatic complications.

VIEW IMAGE

FIGURE 7-6 Lateral plain film shows a nasal fracture through the frontonasal suture (*arrow*) with posterior displacement of the nasal bones.

Isolated Maxillary/Palatal Fractures

Alveolar fractures are the most common isolated maxillary fractures. An upward blow to the mandible can thrust the mandible into the maxilla and push the maxillary teeth upward and outward. This movement, in turn, fractures the alveolus. Because of the strong soft-tissue support over the alveolus, these isolated fractures rarely are displaced. The involved teeth often are displaced or devitalized, and such alveolar fractures in children may damage the tooth germs.[7] Partial fractures of the maxilla can result from a blow delivered by a narrow object directly over the anterior maxillary wall. The fractures usually involve the anterior and lateral antral walls and extend toward the pyriform aperture and down into the maxillary alveolus (Figs. 7-9 to 7-12).

Sagittal fractures of the palate result from either an axial or an oblique blow to the chin or a direct blow to the upper jaw. The fracture passes through the weakest portion of the palatine process of the maxilla, which is in a sagittal plane just off of the midline. The midline itself is reinforced by the vomer, whereas the lateral hard palate is supported by the alveolus. In more violent trauma a sagittal midline fracture can occur, and comminuted palatal fractures are associated with other central or centrolateral facial fractures.[7]

Le Fort I Fractures

The Le Fort I (Guérin's) fracture results from a blow delivered over the upper lip region and is characterized by detachment, at a level just above the floor of the nasal cavity, of the upper jaw with the tooth-bearing segments from the caudal portions of the maxillary sinuses and the lower nasal septum. The fracture extends through the lower nasal septum, the lower walls of the maxillary sinuses, and the lower pterygoid plates. Thus the fracture segment includes the entire palate, maxillary alveolus and teeth, and portions of the pterygoid plates. This ''floating palate'' is displaced posteriorly, resulting in malocclusion and hemorrhaging into the antra (Figs. 7-13 and 7-14).[7]

The presence of upper arch dentures can modify the fracture patterns occurring in midfacial trauma. In a group of such patients with predominantly Le Fort I fractures, an atypical fracture path was noted, with a vertical fracture passing from the main Le Fort I fracture to the inferior orbital rim. Full upper arch dentures generally protected the upper alveolus from fracture but, where there was discontinuity of the prosthesis, alveolar fractures mirrored the edge of the denture as it crossed the alveolus. Thus the clinician should be alerted to the possibility of unusual maxillary fractures in denture wearers.[27]

There are also fractures of the ethmoids with some hypertelorism. Axial CT scan (**C**) shows a nasoorbital fracture with posterior and medial displacement of both nasal bones and each frontal process of the maxilla. There are also multiple fractures of the ethmoid complex and some hypertelorism. Axial CT scan (**D**) shows a nasoorbital fracture with posterior displacement of the nasal bones and fractures and hypertelorism of the ethmoid complex.

Le Fort II Fractures

A strong, broad blow over the central facial region causes a pyramidal fracture, one of the most severe midfacial fractures. The high, central midface fracture (Le Fort II) is characterized by a fracture line that extends through the root of the nose, then runs bilaterally to involve the lacrimal bones and medial orbital walls. On each side the fracture line then turns anteriorly along the floor of the orbit near the infraorbital canal and extends down the zygomaticomaxillary suture and the anterior wall of the maxilla; posteriorly the fracture goes down across the infratemporal surface of the maxilla and finally extends through the lower pterygoid plates. This creates a pyramid-shaped central facial fracture segment. The deep central midface (Wassmund I) fracture spares the nasal bones and extends from the lateral edges of the pyriform aperture back across to the lacrimal bones and into the medial orbital walls. From this point the fracture is the same as the Le Fort II (Figs. 7-15 and 7-16).[7] In the Le Fort II and Wassmund I fractures the zygomatic bones remain attached to the cranium. The pyramid-shaped fracture segment (the central midface) is posteriorly displaced, resulting in a ''dishface'' deformity, malocclusion, and hemorrhage. Anesthesia or paresthesia of one or both of the infraorbital nerves occurs in 78.9% of the cases.[10]

Le Fort III Fractures

Centrolateral midfacial fractures are characterized by separation of the entire facial skeleton from the skull base. Such a craniofacial dysjunction has a fracture line that extends through the root of the nose, then runs bilaterally across the lacrimal bones and medial orbital walls, to continue posterolaterally across the floor of each orbit to the inferior orbital fissure. At this point on each side, one portion of the fracture line extends laterally and upward across the lateral orbital wall to end near the zygomaticofrontal sutures. A second fracture line extends from the

orbital floor down across the back of each maxilla to the lower portion of the pterygoid plates. The zygomatic arches also are fractured, thereby completing the separation of the facial skeleton from the skull base. Such a fracture is called a Le Fort III or Wassmund IV fracture (Figs. 7-17 to 7-19). The same fracture without inclusion of the nasal bones is called a Wassmund III fracture (Fig. 7-17B), and the fracture line extends from each side of the pyriform aperture up to the lacrimal bones. The fracture then continues as a Le Fort III fracture. The distinguishing feature between the Le Fort III fracture and the Le Fort II fracture is the inclusion in the Le Fort III fractured segment of the zygomas and lateral orbital walls. These patients have a dishface deformity, CSF rhinorrhea, hemorrhage, damage to the lacrimal apparatus, and malocclusion. The infraorbital nerves are involved in 69.3% of cases.[10]

LATERAL MIDFACIAL FRACTURES

Lateral midfacial fractures include the zygomatic fractures (trimalar, or tripod), zygomatic arch fractures, zygomaticomaxillary fractures, zygomaticomandibular fractures, and fractures of the floor of the orbit (blow-out fractures).

Trimalar (Zygomatic) Fractures

Zygomatic fractures are the second most common facial fractures after nasal bone trauma. The fracture line in a zygomatic fracture extends from the lateral orbital wall (zygomaticofrontal suture and the zygomaticosphenoid suture) to the inferior orbital fissure, then across the orbital floor near the infraorbital canal, down the anterior maxilla near the zygomaticomaxillary suture, and up the posterior maxillary wall back to the inferior orbital fissure. There is also a fracture through the weakest part of the zygomatic arch, which is about 1.5 cm dorsal to the zygomaticotemporal suture. The infraorbital nerve is impaired in 94.2% of the cases.[10] These fractures are usually and traditionally referred to as trimalar or tripod fractures because these are fractures through the three bony connections of the zygoma. That is, there are fractures (1) through the lateral orbital wall, (2) separating the zygoma and maxilla, and (3) through the zygomatic arch. Rarely these fractures have been referred to as quadramalar fractures, because the fractures extend through four suture lines (zygomaticofrontal, zygomaticosphenoid, zygomaticotemporal, and zygomaticomaxillary). Nonetheless, the more common term is trimalar fracture, recognizing that there is one fracture line through the

lateral orbital wall that actually goes through two suture lines (zygomaticofrontal and zygomaticosphenoid).

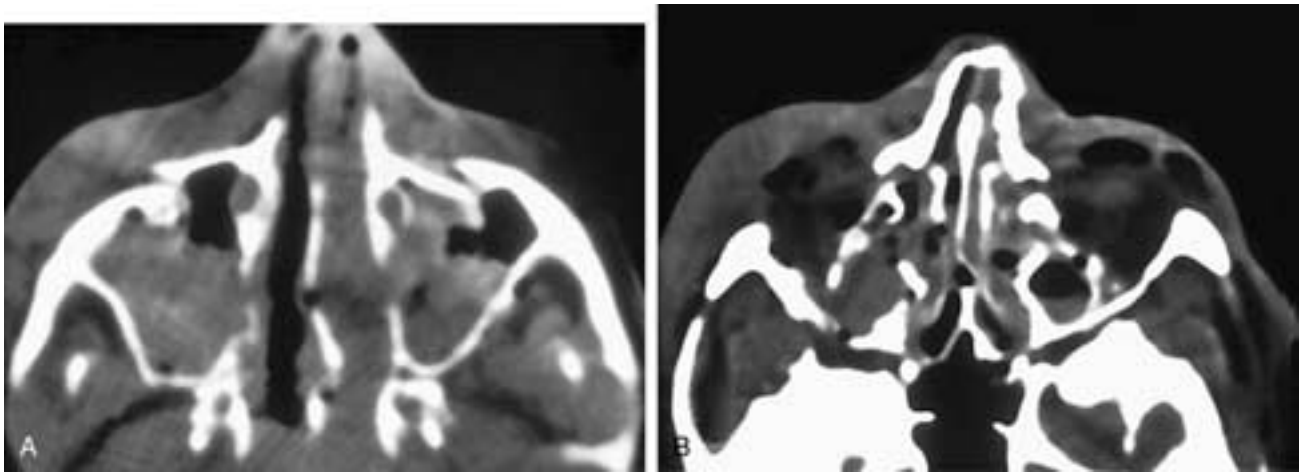
In one study, as many as one-third of all patients who suffered comminuted malar fractures had an ocular disorder, but only 16.7% of patients with a blow-out fracture had ocular problems. Decreased visual acuity was the primary problem accompanying the majority of significant eye injuries.[28–30]

Several classifications of lateral midface fractures have been proposed.[31] Each considers the displacement of the zygoma as it relates to the clinical severity of the fracture and how the malar position may be used to plan treatment. Zygomatic fractures account for 49% to 53% of the midface fractures, and in one study 69% of midfacial fractures involved the zygomatic complex, either alone or in combination with other midface fractures.[7, 31] The reports vary considerably as to the frequency of the different malar fracture positions. One of the more complete classifications, including the fracture type, frequency, and postreduction stability, is shown in Table 7-1.

Table 7-1
TYPE, FREQUENCY, AND POSTREDUCTION STABILITY OF ZYGOMATIC FRACTURES

Fracture Type	Frequency	Postreduction Stability (%)
Nondisplaced	11	100
Isolated arch	16	93
Rotation around vertical axis	12	
Medial	3.5	57
Lateral	8.5	88
Rotation around horizontal axis	6	
Medial	10	
Lateral	5	50
Displacement without rotation	31	
Medial	11.5	39
Lateral	1	0
Posterior	12	92
Inferior	6.5	0
Isolated rim	9.5	47
Complex	14.5	0

Before the use of miniplates and microplates, this type of classification allowed the clinician to better predict the postoperative stability of the fracture and thus influence the degree of fixation needed (Figs. 7-20 to 7-25). When the malar eminence is rotated in more than one axis or displaced in more than one direction, the primary rotation and displacement are usually used to classify the fracture. However, these complex cases point out the limitation of any of these classification systems. In the present era, the use of miniplates and microplates is common, and there is little



VIEW IMAGE

reliance on a classification system to determine the treatment type. It is used by the few surgeons who believe that not all zygomatic fractures need fixation after reduction. It is generally believed that the primary cause of movement of a reduced but nonfixed malar fracture is the masseter muscle's pulling force on the zygoma.[32]

Zygomaticomaxillary Fractures

Zygomaticomaxillary fractures differ from trimalar fractures in that the former fractures include a maxillary segment. Thus, a zygomaticomaxillary fracture involves the orbital floor, extends down the anterior maxilla (often more medially than in a typical trimalar fracture) near the infraorbital foramen, runs to the premolar region, and then extends across the palate to the maxillary tuberosity and lower pterygoid plates.

Zygomaticomandibular Fractures

Zygomaticomandibular fractures differ from zygomatic fractures only by the additional fracture of the mandibular condyle, coronoid process, or both.

Zygomatic Arch Fractures

When there are isolated fractures of the zygomatic arch, there usually are at least three discrete fracture lines, creating two fracture segments. These pieces are displaced medially and downward, reflecting the direction of the impact force. The fracture pieces may impinge on the temporalis muscle or coronoid process of the mandible and interfere with movement of the lower jaw (Figs. 7-26 and 7-27). Trismus is reported in 45% of zygomatic arch fractures and in about 33% of all zygomatic fractures.

Hemorrhage is present in the right antrum, and a small amount of orbital emphysema is present.

Blow-out and Blow-in Orbital Wall Fractures

Fractures of the orbital floor may occur as either simple or comminuted fractures in conjunction with midfacial fractures, with atypical periorbital fractures (orbital roof), or as isolated blow-out fractures.

The term *orbital blow-out fracture* describes the injury that results from a blow to the orbit by an object that is too large to enter the orbit (fist, baseball, etc.). The force of the blow is absorbed by the orbital rim and is transmitted to the thinner orbital floor, which shatters, usually in the middle third near the infraorbital canal (presumably the floor is

weakened by the presence of the infraorbital canal, which is often also dehiscent). As the eye is pushed back into the conical orbital apex, it increases intraorbital pressure and this ''blows out'' the fractured floor into the maxillary sinus. Usually the orbital rim is not fractured (pure blow-out fracture) and the globe remains undamaged. Less commonly the inferior orbital rim also is fractured; this is referred to as an impure blow-out fracture. Blow-out fractures represent only 3% to 5% of all midface fractures (Figs. 7-28 to 7-34).[33]

Herniation of orbital fat, inferior rectus muscle, and inferior oblique muscle can occur with occasional muscle entrapment in the fracture line, resulting in diplopia on upward gaze. However, diplopia is the most frequent complaint in all patients with blow-out fractures and may occur solely because of periorbital edema and hemorrhage, which exert pressure on the globe. This type of diplopia resolves in several days, whereas entrapment diplopia remains. If the cause of diplopia is in doubt, a traction test can be performed on the inferior muscles. Rarely a depression fracture of the orbital roof or superior orbital rim can impinge on the upper globe, prohibiting upward gaze and clinically mimicking an inferior muscle entrapment (Fig. 7-35). Imaging studies clarify this situation. In these

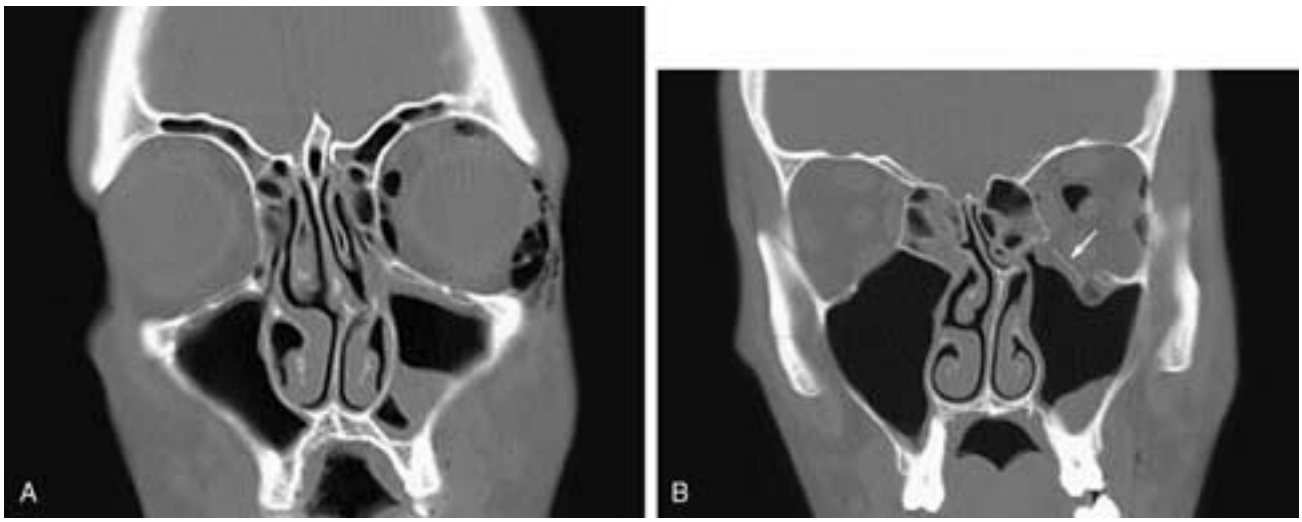
latter cases, communication with the base of the anterior cranial fossa can lead to CSF leakage into the orbit or herniation of meninges or brain through the fracture line.

Rarely the orbital floor fracture segments can herniate upward into the orbit, impinging on the inferior orbital muscles or the globe. This unusual occurrence has been called a blow-in fracture, and on imaging it must be clearly identified so that the clinician can reposition this fractured bone. Laceration of the globe can rarely occur.[10, 34]

Despite the fact that many reports have indicated that the middle third of the orbital floor is the weakest portion of the orbit, the thin lamina papyracea of the medial wall should theoretically be the weakest area. In one study of clinically suspected orbital blow-out fractures evaluated with CT scans, the most common fracture was an isolated medial wall fracture (55%), followed by medial and inferior wall fractures (27%). The most common facial fracture associated with a medial wall fracture was a nasal fracture (51%), not an inferior wall fracture (33%). This suggests that the force causing a nasal fracture is an important causative factor in creating a pure medial wall fracture. Of patients with medial wall fractures, 25% had diplopia and 40% had enophthalmos.[35]

In another article analyzing 2741 patients with facial fractures, 273 patients (9.9%) were identified with 304 medial orbital wall fractures. The male-to-female ratio was 5:1, and most injuries involved the left orbit. Most fractures were caused by fist fights, but more complex injuries were noted secondary to car accidents and falls. The fractures were divided into types based on the location and severity of



VIEW IMAGE

the injury. Type I fractures were confined to the medial orbital wall. Type II fractures involved the medial orbital wall and continuous orbital floor. Type III fractures involved the medial orbital wall and orbital floor and malar fractures. Type IV fractures involved the medial orbital wall and complex midfacial injuries. Although visual loss (2%), diplopia (41%), and enophthalmos (12%) were seen, diplopia and enophthalmos were commonly observed with type II injuries. Imaging studies showed that about 52% of the fractures were associated with prolapse of orbital fat, but only 43% could be diagnosed on plain films.[36]

Thus, fractures of the medial orbital wall can occur either as isolated fractures or in conjunction with orbital floor fractures or more complex fractures. Traditionally, such medial wall fractures were considered to accompany nearly 50% of orbital floor fractures, but as discussed, the incidence may be far greater. Often the ethmoid fracture is poorly visualized on plain films, with only some clouding of the

ethmoid cells being evident. Even on CT scans, if there is no bone displacement, the actual fractures may not be identified. However, on CT, fat that has herniated into the fractured ethmoid complex is well visualized (Figs. 7-36 to 7-41). Herniated fat can also be identified on MR imaging, although small fracture segments may not be identified. Muscle entrapment in these fractures is rare.[37] The only imaging differential diagnosis is a congenital dehiscence of the lamina papyracea (actually, a hypoplasia of the ethmoid complex). In congenital dehiscence, on CT and MR imaging, portions of the lamina papyracea are either not visualized or are medially bowed and orbital fat lies in the ethmoid complex. However, unlike in trauma cases, the margins of the defect are smooth and there is no history of trauma.

Medial wall fractures can also be inferred by the presence of orbital emphysema. Such orbital air most commonly comes from an ethmoid sinus fracture and rarely results from an isolated maxillary fracture. The infrequent occurrence of orbital emphysema with orbital floor blow-out fractures is attributed to the rapid sealing of the fracture by edema, hemorrhage, and periorbital herniation of orbital fat

and muscle. Orbital emphysema develops after an ethmoid fracture when nose blowing by the patient increases intranasal pressure, which in turn raises the intrasinus pressure and forces air into the orbit. In most patients, refraining from nose blowing allows the fracture line to seal and the orbital air to resorb.[10]

Rarely, air can enter the orbit from a complex fracture involving the frontal or sphenoid sinuses. However, these cases are associated with severe facial trauma, and the source of the air becomes evident on imaging studies. Even more rarely, pneumomediastinum can occur following a blow-out fracture.[38]

The two clinical indications for immediate surgery on an orbital blow-out fracture are definite muscle entrapment and acute enophthalmos. In the most dramatic case, the globe is almost completely displaced into the maxillary sinus and there are reports of complete globe herniation into a fractured maxillary sinus.[39–41] However, milder and more common degrees of acute enophthalmos may take several days to confirm clinically because of the presence of periorbital edema and hemorrhage.

The development of chronic enophthalmos is also to be avoided, because it leads to cosmetic deformity and in some cases diplopia. Chronic enophthalmos develops when too much orbital fat has herniated from the orbit. Although initially the increased orbital volume clinically goes unnoticed because of compensatory intraorbital edema, the subsequent loss of edema, scarring, and lipogranulation of the herniated tissues eventually cause sufficient volume loss that the globe recedes. The patients who are at greatest risk are those who have sizable herniations of fat into one sinus (maxillary or ethmoid) or moderate herniations into both medial wall and orbital floor fractures. The imager must draw the clinician's attention to any such cases that may have the potential to develop chronic enophthalmos, even in the absence of acute enophthalmos or muscle entrapment.

Alloplasts are often used to reconstruct the orbital floor where they have been effective in the long-term reconstruction of this orbital margin. However, such products rarely work effectively in the long-term attempted repair of the medial orbital wall, as invariably there is movement of the alloplast. The products most often used include Teflon, Silastic, and Marlex mesh, all of which have the benefit of not being absorbed.[42] However, these alloplasts have the disadvantages of extrusion and infection. They can be identified on CT, which is a useful modality to detect early displacement of the graft.

On plain films, soft-tissue swelling over the inferior orbital rim, antral opacification with or without an air-fluid level, and subcutaneous emphysema in the cheek are often the only indirect signs of a blow-out fracture. An actual depressed or displaced orbital floor bone fragment may not be seen. Occasionally a soft-tissue polypoid density can be visualized in the antral roof. This may represent the site of the blow-out fracture filled with orbital contents and hemorrhage or it may represent an unrelated antral cyst or polyp. Only on coronal CT or MR imaging can the actual fracture and herniated tissue be clearly seen. A completely displaced piece of bone, a trapdoor fracture, or a hinged fracture can then be identified, as can the typical ''teardrop'' herniation of orbital contents. On CT the orbital fat may be of a higher attenuation than expected because of hemorrhage; in some cases an antral air-blood level may be present.[22] On MR imaging, the high T1-weighted signal intensity of the orbital fat and any hemorrhage can be well seen; however, a small bone fracture segment may not be identified.

Supraorbital roof fractures are uncommon, and the incidence has been reported to be between 1% and 5%. In one study of 621 patients with facial fractures, 9.3% had supraorbital roof fractures. The average age of these patients was 31 years, and the predominant mechanism of injury was from motor vehicle accidents. Sixty-nine percent of the patients had associated skull fractures and 54% had frontal sinus fractures. Dural tears were present in 14 patients, traumatic encephalocele in 3, proptosis in 6, pulsatile proptosis in 3, orbital apex syndrome in 1, persistent CSF leak in 3, and meningitis in 5. A majority of the patients had associated intracranial bleeds.[43]

FRONTAL SINUS FRACTURES

Frontal sinus fractures are the result of either direct trauma or an extension of a calvarial fracture into the sinus. Of all the fractures involving the frontal sinuses, 67% are limited to the anterior table, 28% involve both the anterior and posterior sinus walls, and only 5% are limited to the posterior sinus table.[44] Most commonly a linear fracture occurs in the anterior sinus wall. This fracture tears the mucosa and produces hemorrhage, edema, and sinus opacification. The fracture line may extend downward, often involving the superomedial orbital rim (Figs. 7-42 to 7-48).

Comminuted fractures of the anterior wall also occur and frequently reflect the size and shape of the object causing the fracture. On plain film Caldwell and Waters views, only a vague density may appear in the frontal sinus. However, on a lateral view, bone fragments may be identified within the sinus. Axial CT most clearly confirms the presence of such depressed fractures, which often are clinically unobserved because the forehead soft-tissue depression is filled by edema and hemorrhage.[45]

Complex fractures of both the anterior and posterior frontal sinus tables usually are associated with other midfacial fractures. Isolated fractures of the posterior sinus wall are rare. They occur either as an extension of a skull base fracture or as an extension of a calvarial fracture.[46–49] Any fracture involving the posterior frontal sinus wall opens communication with the dural spaces, and CSF leakage into the sinus and intracranial infection or a pneumocele can develop. Rarely, orbital emphysema or CSF leakage into the orbit can result from frontal sinus fractures. In one study of CT scans on patients with suspected intracranial posttrau-

matic injuries, 90% of the patients had a frontal sinus fracture identified on the initial CT scan. Complex fractures involving the anterior and posterior walls accounted for 65% of the cases, and isolated anterior wall (24%) or posterior wall (11%) fractures were less common.[45] This study reflects the severity of the trauma that led to both the fractures and the intracranial damage. In fact, it has been determined that it takes two to three times the force to fracture the frontal sinus than it does to fracture the zygoma, maxilla, or mandible.[50]

In general, nondisplaced frontal sinus fractures are treated conservatively. Uncomplicated anterior table fractures with cosmetic deformity are treated by fragment reduction and stabilization, usually with microplates or miniplates. Nasofrontal duct obstruction is usually managed by sinus obliteration. Finally, comminuted, displaced anterior and posterior table fractures, especially those associated with persistent CSF leakage, are often treated by frontal sinus cranialization.[47]

SPHENOID SINUS FRACTURES

Fractures of the sphenoid sinus seldom occur, but when they do, they are associated with severe cranial trauma and basilar skull fractures. Often, these patients are recumbent due to the associated intracranial injuries. In these cases, sphenoid opacification or a sphenoid sinus air-fluid level may indicate intrasinus hemorrhage, leakage of CSF directly into the sinus from a sphenoid sinus fracture, CSF drainage into the sinus via the nasopharynx from a temporal bone fracture in a patient with an intact tympanic membrane, poor sinus drainage due to supine position, and edema around indwelling nasogastric or orotracheal tubes. Rarely, milder trauma to the midfacial region may extend back into the sphenoid sinus. If the fracture injures the adjacent internal carotid arteries or cavernous sinuses, these events may be life-threatening.

PEDIATRIC FACIAL FRACTURES

When compared with the adult skeleton, the pediatric facial bones behave differently with regard to fracture patterns, healing, and treatment. The inherent elasticity of the facial bones in a young patient is advantageous in trauma because the bone yields more easily and does not fracture as readily as it does in an adult.[1] When a fracture does occur, the thick, elastic periosteum usually prevents bone displacement and a green-stick fracture results. In addition, fractures heal faster in children than in adults, so the period of immobilization is shorter. However, if treatment is delayed, the fragments may become fixed, making fracture reduction more difficult. Malocclusions in the primary dentition that are not completely corrected may be spontaneously compensated for by the secondary dentition or may be treated by orthodontic therapy.[1]

Although children have many advantages in terms of healing, they are at a disadvantage with regard to dentition. In 30% to 50% of pediatric facial fractures, the tooth germs lie in the fracture. These teeth fall out during healing or have delayed development and deformities that do not manifest clinically until the permanent teeth erupt. Facial fractures also can damage the bony growth centers and result in osseous hypoplasia, functional abnormalities, and cosmetic deformities. Some clinicians believe that the child's parents should be informed of these potential problems at the time of the initial injury.

Children generally have too few teeth for fixation splints,

and treatment plans must be modified from those used in adult patients. No wire ligatures can be placed in children under 2 years of age. After this age, it may be possible to fix interdental wires and arch bars if the primary teeth have not been damaged by caries and their crowns have an adequately retentive form. However, with the appearance of interdental spaces caused by eruption of the secondary teeth, the possibility of fixing dental splints becomes less likely. Similarly, erupted permanent teeth can accept such ligatures only after their greatest convexity has passed the gingival margin. This period lasts from about the fifth to the eighth years of life.[1]

SECTION TWO

POSTOPERATIVE SINONASAL CAVITIES

IMAGING EVALUATIONS

The proper imaging evaluation of the postoperative patient requires the radiologist to be knowledgeable about a number of facts, some of which are often obscure at the time of performing and then interpreting the imaging examination. Ideally, the radiologist should know what operation was performed, when it was done, and what disease prompted it. Familiarity with the various surgical procedures enables the radiologist to determine which bone(s), if any, can be expected to be removed, what soft-tissue defects may be created, and what soft tissue or foreign material is usually placed to repair the surgical defect. This knowledge is essential for proper imaging interpretation and should help prevent the misdiagnosis of a surgical defect as a site of bone erosion or a muscle-fascia graft as a tumor recurrence.

The interval between the surgery and the time of imaging helps the radiologist determine the type of soft-tissue reaction to expect. For recent surgery, the primary healing reaction is active inflammation with edema and possible hemorrhage. However, if the surgery was performed months to years ago, the primary expected healing reaction is mature granulation tissue or vascularized scar with varying degrees of fibrosis. In some patients, a reactive bony sclerosis may occur after those procedures that denude mucosa. Such a reaction requires time to develop and produce sufficient bone thickening to possibly reduce the sinus cavity size. This is a reactive process to the surgery and, although it may appear the same on imaging as the sclerosis associated with chronic inflammation, there is no evidence of active disease or pain in the majority of these patients. However, in some patients, recurrent sinusitis can coexist with the reactive postoperative changes. In these cases, one cannot know whether the bone changes are attributable to the active inflammation, the postoperative reaction, or both.

Knowledge of the disease process that initially prompted the surgery allows the radiologist to anticipate the types of imaging changes to expect. Thus, if the initial disease was chronic infection, one may commonly expect recurrent sinus mucosal thickening, reactive bone sclerosis and thickening, and possible nasal polyposis. If the initial disease was a granulomatous process, one may expect sinus mucosal thickening, nasal mucosal changes, septal erosions, and bone erosions intermixed with areas of reactive bone. If the initial disease was a tumor, the concern will be to characterize any nodular or localized soft-tissue disease, differentiate recurrent tumor from infection, and observe the presence of progressive bone erosion or soft-tissue extension to areas not normally involved by the surgery.

The best and most efficacious way to interpret a

Copyright © 2003, Mosby, Inc. All rights reserved.

postoperative imaging study, especially on a patient with a malignancy, is to compare it with a prior examination. Initially, this is best accomplished by comparing a follow-up study to a baseline postoperative CT or MR examination. This baseline scan is important for the imaging monitoring of a patient after surgery because it provides an anatomic reference with which all future examinations can be compared. If this baseline study is obtained too close to the time of surgery, the imaging findings are dominated by changes of hemorrhage and edema and thus may give a false impression of what the eventual stable postoperative appearance will be. However, if one waits too long after surgery, recurrent disease may be present. The best compromise appears to be a postoperative waiting period of 6 to 8 weeks. This time allows most of the hemorrhage and edema to resolve, whereas few if any tumors (or chronic inflammatory diseases) will recur within this period.[51, 52]

Although the baseline study is less important in patients with inflammatory disease, it still provides a reference standard against which future imaging studies can be compared, and a few physicians routinely obtain such a study for future comparison.

On subsequent follow-up CT or MR examinations, any progressive soft-tissue resolution can be interpreted as a further reduction of any postoperative edema and inflammation. However, the appearance of any new soft-tissue changes, or sites of bone erosion, must be considered recurrent disease until proven otherwise. Patients who have been operated on for inflammatory disease usually do not need periodic follow-up scans and are only imaged if symptoms reappear. By comparison, those patients who have been operated on for tumors should have scheduled periodic follow-up scans if early tumor recurrences are to be diagnosed. The time interval between these examinations usually is 4 to 6 months for the first 2 or 3 postoperative years and then 6 to 12 months for the next 2 to 3 years.[51, 52]

Plain films do not allow detailed evaluation of the postoperative patient because of the overall survey nature of these studies and the unique anatomy of the paranasal sinuses, where focal soft-tissue disease is best assessed by its relationship to the adjacent bone (which may now be resected) and sinus cavity air (which may be obscured by fibrosis or disease). Thus CT and MR imaging are the examinations of choice in monitoring the course of postoperative patients. CT allows the detailed evaluation of bone and a fairly accurate assessment of the soft tissues, provided that both axial and coronal views are available. The use of contrast is desirable because it provides some distinction between inflammatory tissue, tumor, and scar.

MR imaging offers the possibility of further differentiating recurrent tumors from sites of active infection. However, even when contrast is used, the distinction between vascularized scar and tumor may be impossible and early bone erosions may go undetected.[53] Tumor invasion into marrow-containing bone is, however, usually detected earlier on MR imaging than on CT.

Ultimately the examination of choice depends on the surgical procedure and the disease. In general, recurrent inflammatory disease is best followed on CT. The appearance of mucosal thickening is easily identified, and interval changes can be assessed by comparison to a previous CT study.

The radiologist is presented with more serious diagnostic problems when following a patient with a tumor, as the distinction between inflammatory disease, scar, and tumor is of critical importance. On CT, inflammatory secretions and reactions tend to have lower attenuation than most sinonasal tumors. On contrast-enhanced CT, active inflammatory changes tend to enhance more than most tumors. However, variations in this pattern commonly exist, and in many cases vascularized scar tissue cannot be confidently differentiated from either inflammation or tumor.

On MR imaging, inflammatory tissues usually have a low to intermediate T1-weighted and a high T2-weighted signal intensity. As mentioned in Chapter 6, about 95% of sinonasal tumors have intermediate signal intensity on all imaging sequences. Thus, in most cases, a good distinction can be made between tumor and adjacent inflammation.[54] On contrast-enhanced MR imaging, inflammatory tissues enhance intensely, and they tend to follow the contour of the sinus cavity wall fairly smoothly. Tumors, on the other hand, usually enhance only moderately and have a distinctly nodular configuration. As mentioned, the vascularized scar tissue that often develops in the postoperative sinonasal cavities has the identical imaging characteristics as tumor on both CT and MR imaging. Ultimately the distinction between these tissues is made either by comparing the imaging findings on serial studies or by biopsy of any suspicious regions. In general, MR imaging is the preferred modality to follow patients with sinonasal tumors. Newer approaches to detect early tumor recurrence include the use of MR spectroscopy and PET scanning. These topics are discussed in Chapter 45.

OPERATIVE PROCEDURES

NASAL SURGERY

Although surgery on the nose is primarily cosmetic, posttraumatic airway reconstruction accounts for many procedures. Surgery confined to the nasal or septal cartilages rarely leaves an imaging identification. However, during a rhinoplasty, use of the saw, chisel, and file to remove bone leaves a slight irregularity along the midline contour of the nasal bones. This is best seen on lateral plain films of the nose (Fig. 7-49). The nasal bones are also purposely fractured in cases of nasal bone ''hump'' removal. Once this bony mound has been removed, the resulting broad nasal base is cosmetically too wide. Because of this, the lateral nasal walls are fractured and turned inward, re-creating a thin midline nasal contour. Such iatrogenic fractures may mimic a recent traumatic fracture, and only the patient's history may resolve any confusion. After 6 to 12 months, the sharp edges of all nasal fractures become smooth, and the fracture lines are less sharply identified. Old fractures also can prove confusing when evaluating recent nasal trauma.

In more severe nasal injuries in which the nasal bones have been crushed, cartilage or rib implants may be used to reconstruct a normal nasal contour. These implants give a unique radiographic appearance that, once identified, indicates to the imager that reconstructive surgery was performed (Figs. 7-50 to 7-52).

VIEW IMAGE

FIGURE 7-49 Lateral plain film shows a patient who has had a prior rhinoplasty. The irregularity of the nasal bone contour is postsurgical in etiology.

The topics of endoscopic sinonasal surgery and the postoperative complications associated with this surgery are covered in Chapters 3 and 4. The following discussion concerns those more classic, nonendoscopic operations.

FRONTAL SINUS SURGERY

Trephination

Statistically, most frontal sinus disease stems from infection and can be classified as acute or chronic. In acute infections, especially if an air-fluid level is found on plain films or imaging, factors such as the time to diagnosis and the patient's immediate response to treatment determine whether a trephination (essentially an incision and drainage) procedure should be performed. The operation consists of drilling a small hole 0.5 to 1 cm to the side of the midline, usually near the upper edge of the eyebrow. After the sinus is entered and drained (the sinus mucosa is not stripped), a drainage tube or cannula is placed in the sinus for 8 to 14 days, after which it is removed to prevent a foreign body reaction in the sinus mucosa.[55] Most often the surgeon determines, by means of a Caldwell view, the sinus size and the presence of any sinus loculations. Care must be taken so that the drill does not enter either the orbit below, the anterior cranial fossa through the posterior sinus wall, or, for a small sinus, the calvarium outside of the sinus margin. The surgical defect is poorly visualized on coronal and axial CT unless the scans happen to pass directly through the site (Fig. 7-53). If the scan is performed while the drain is in place, the drain can be followed to its exit point from the sinus.

nonobliterative procedures: the Lynch, Killian, and Riedel procedures. For the most part, these operations have been replaced by endoscopic approaches or, for large sinuses, the obliterative osteoplastic flap procedure.

Lynch Procedure

The Lynch procedure is utilized primarily for disease in the ethmoid sinuses and supraorbital ethmoid cells. However, it also provides good entrance into a small to moderate-sized frontal sinus. The Lynch incision is buried in the creases and concavity of the lateral nose and the superomedial orbital margin. The frontal sinus is entered from below and behind the orbital rim, and the region of the nasofrontal duct is exposed by a lateral (external) ethmoidectomy. The diseased frontal sinus and ethmoid mucosa are removed, and a tube is placed in the nasofrontal duct to promote sinus drainage through a reconstructed duct. This tube remains in place for 6 to 8 weeks and then is removed intranasally (Figs. 7-54 to 7-56).

If the frontal sinus is too large for all of its diseased mucosa to be effectively removed by the standard Lynch procedure, an extended Lynch incision can be used, extending the incision more laterally over the orbit. Alternatively, in past years, a larger bony defect was made in the anterior frontal sinus wall, using either the Killian or Riedel procedure.

Killian Procedure

In a moderately large frontal sinus the Killian procedure can be used. Via two bony defects, this approach creates a larger entrance into the frontal sinus than can be obtained with an extended Lynch procedure. In the Killian approach the first bony defect is created above the orbital rim in the anterior frontal sinus wall, and the second defect is created below and behind the orbital rim in the frontal sinus floor (via a standard Lynch incision). The intact superior orbital rim partially prevents the overlying soft tissues of the forehead from collapsing into the sinus, and when compared with the Riedel procedure, the resulting cosmetic deformity is minimized (Fig. 7-57). However, the soft tissues of the forehead region do partially prolapse into the sinus cavity and create a noticeable cosmetic deformity, which is well

FIGURE 7-54 Diagram of a Lynch procedure. The ethmoid sinuses, supraorbital ethmoid cells, and small frontal sinuses can be approached by this procedure. The incision is buried in the creases of the lateral nose and the superomedial orbital rim.

seen on axial scans. As in the Lynch procedure, the nasofrontal duct is reconstructed through an external ethmoidectomy.

Riedel Procedure

For the reliable removal of diseased sinus mucosa in a large frontal sinus, the Riedel procedure can be used. In this approach the two surgical defects created in the Killian procedure are joined into one large defect, which includes the superior orbital rim (Fig. 7-58). At the completion of the procedure the soft tissues of the forehead are laid on the posterior frontal sinus wall, which has been denuded of its mucosa. This effectively obliterates the upper sinus cavity but creates a cosmetically undesirable soft-tissue defect in the forehead. The nasofrontal duct is reconstructed as in the Lynch procedure.[55, 56]

Because of the cosmetic deformities associated with these procedures, particularly the latter two techniques, and because the nasofrontal duct becomes obstructed postoperatively in about 50% of these patients, the cosmetically less deforming obliterative osteoplastic flap procedure has gained great popularity, especially in the moderate to large frontal sinuses in which mucosa cannot be removed by a Lynch approach.

Osteoplastic Flap Procedure

The osteoplastic flap incision is either a curved coronal scalp incision that is hidden in the scalp hair or a brow incision that extends between the eyebrows, crossing the intervening skin crease near the root of the nose or nasion. Once the periosteum over the frontal bone is exposed, a template made from a Caldwell view is used to trace the frontal sinus contour on the bone and periosteum. This template should come from a film taken on a dedicated head unit such as the Franklin head unit, which has a magnification factor of only 3.4% (compared with 10.3% on a standard 40-inch posteroanterior Caldwell film).[57] The template is made by cutting out on this film the sinus contour and the contour of the upper orbits. The resulting template is then gas sterilized. The orbital contours can be used to localize the template on the patient, and then the sinus outline is traced on the patient's exposed frontal bone with its intact periosteum.

The periosteum is incised on all except its inferior margin, and the frontal sinus contour is drilled into the anterior frontal sinus table. The drill line is beveled medially and downward into the sinus to help ensure that the frontal sinus and not the anterior cranial fossa is entered. The inferior margin of this anterior wall is not drilled but is fractured from side to side, elevated, and turned downward off of the sinus, with its overlying periosteum intact. This technique yields a viable bone flap. The sinus mucosa is then drilled out, and the sinus cavity is obliterated with fat or muscle, usually taken from the abdominal wall. The anterior sinus wall is then replaced, the periosteum sutured, and the skin closed, leaving literally no cosmetic deformity (Fig. 7-59).

FIGURE 7-59 Diagram of an osteoplastic flap procedure. The anterior sinus wall is flipped down, with the inferior periosteum left intact. After the sinus mucosa and disease are removed, the sinus is obliterated with fat and then the flap is replaced. This procedure leaves almost no cosmetic deformity.

The fat progressively and gradually undergoes fibrosis, usually until the fibrosis represents one-third to one-half the volume of the obliterating material. More extensive fibrosis of the fat does not appear to occur normally. Throughout this fibrosing process, no volume loss occurs so that the sinus remains obliterated.

Infection of the bone flap or the operative margins, with or without associated osteomyelitis, and infection of the obliterating fat are the two most significant complications of the osteoplastic flap procedure. If the infection cannot be controlled with antibiotic treatment, reoperation is necessary. This often necessitates the removal of the anterior sinus wall bone flap, with some resulting inward prolapse of the forehead soft tissues. A plastic reconstruction can then be performed at a later date once the infection is cured.

If the osteoplastic flap procedure was performed to obliterate a mucocele that thinned or destroyed a portion of the posterior or anterior sinus tables, these defects will also be visualized on subsequent imaging studies. On plain films the osteoplastic bone flap is identified by a variably thin zone of lower density at its margins. This zone represents the bone that was drilled out of the frontal table during surgery (Figs. 7-60 and 7-61). In a few cases the flap fit may be so good as to make visualization of the surgical margin almost impossible on Caldwell or Waters views. However, a lateral view clearly shows the beveled surgical defect. In fact, if a history of prior surgery is not obtained, this defect may be misinterpreted as an anterior frontal table fracture (Fig. 7-62). If the sinus margin was altered before surgery, it will remain so after surgery. Thus the mucoperiosteal white line may be absent or replaced by a thick zone of sclerosis, and the sinus contour may be remodeled. Although this appearance can be confusing and suggests that whatever caused these changes is still present in the sinus, these sinus alterations merely reflect whatever process originally necessitated the surgery. The fat used to obliterate the sinus usually causes the sinus to have a hazy soft-tissue density on plain film, suggesting sinusitis. The surgical bony margins should be sharp and of a normal texture even though the bone flap does not fit precisely against the adjacent frontal bone. An air-fluid level indicates reinfection of the sinus, a serious complication.

On CT the bone flap may go unnoticed if only narrow window images are available. At wide window settings the bone flap should have a normal texture (Fig. 7-63). However, the edges of the flap and the adjacent frontal bone occasionally have a ragged, irregular appearance that reflects the beveling surgical procedure. Without any associated clinical or soft-tissue changes of infection, this irregular bone should not elicit a diagnosis of osteomyelitis. Frank osteomyelitis appears as areas of bone demineralization, erosion, or sequestration accompanied by swelling and cellulitis of the overlying forehead soft tissues. There usually is also evidence of infection in the underlying fat (Fig. 7-64).

FIGURE 7-60 Waters view shows a patient after bilateral osteoplastic flap surgery. The flap margins can barely be identified (*arrows*).

VIEW IMAGE

The bone flap should be in a normal alignment with the adjacent frontal bone contour, that is, the flap should not be either depressed into the sinus or elevated over the adjacent frontal bone. When the flap is elevated, infection of the underlying obliterating fat must be considered. The obliter-

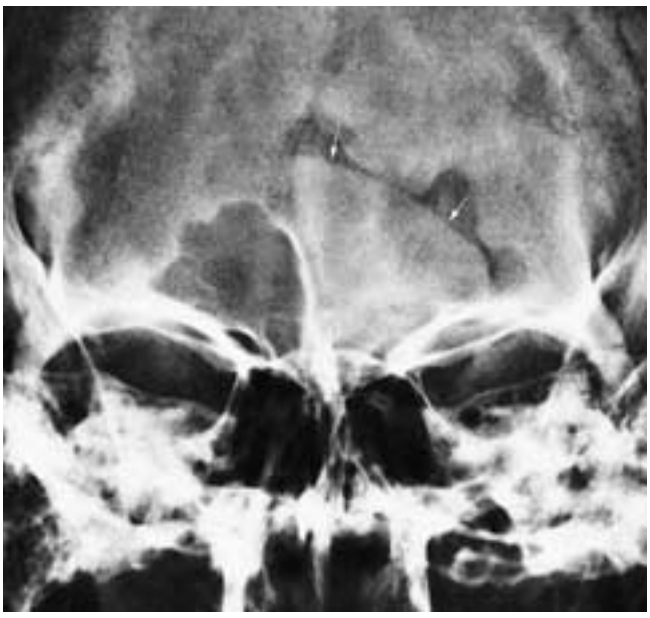

FIGURE 7-61 Caldwell view shows a patient after left osteoplastic flap surgery. The margins of the flap are well seen (*arrows*). The space between the flap and the calvarium is a normal postoperative finding resulting from the bone removal that occurs during surgery.

ated sinus is best examined at both narrow and wide windows. The entire sinus cavity should be airless and filled with fat that has randomly scattered strands of soft-tissue-dense fibrous tissue. Whenever a focal mass of soft-tissue density is seen within the fat or whenever more than half of the fat content is of fibrous density, the imager should raise the possibility of infection (Figs. 7-64, 7-66, and 7-68 to 7-70). This type of infection is usually associated with elevation of the flap secondary to swelling of the fibrous fatty material (Figs. 7-65, 7-69, and 7-70). In these cases the intracranial compartment should also be examined for evidence of spread of the infection.

Occasionally the osteoplastic bone flap fractures during surgery; however, as long as the overlying periosteum remains intact, the fracture pieces usually remain viable. The imager should verify that the bony pieces have a normal texture, that there are no sites of osteomyelitis, and that the bone fragments are not elevated. In rare instances after many years, some calcification can occur in the obliterating fat; this should be considered a normal postoperative variant.

On MR imaging the signal intensities in the normal postosteoplastic flap sinus reflect the obliterating fat. Thus there is a high T1-weighted and an intermediate T2-weighted signal intensity (Fig. 7-71). Although infection in the fat will produce a high T2-weighted signal intensity, occasionally areas of high T2-weighted signal intensity are seen in noninfected sinuses (Fig. 7-72). The precise cause of this is unclear. Thus, the mere presence of a high T2-weighted signal intensity within the obliterating fat should not warrant a diagnosis of postoperative infection. Infection should be considered if there is high T2-weighted signal intensity in the obliterating fat, elevation of the bony flap, and evidence of swelling and inflammation in the surrounding forehead soft tissues.

ETHMOID SINUS SURGERY

Although today the ethmoid sinuses are most often approached endoscopically, traditionally the ethmoid complex can be partially resected via three major approaches: the external, the internal (intranasal), and the transmaxillary (transantral) (Fig. 7-73). These procedures are performed for inflammatory disease, and the aim is to progressively remove the disease from each cell until all of the pathologic material is extirpated. The primary areas of complication are entrance into the floor of the anterior cranial fossa and damage to the orbital contents.[51, 52, 57]

External Ethmoidectomy

The external approach provides the best overall access and visualization of the ethmoid cells. After a Lynch incision, the periorbita is elevated and the surface of the lamina papyracea is viewed to identify prior fractures and any areas of dehiscence or erosion. The anterior and posterior ethmoidal canals are exposed. A line connecting these canals lies just below the floor of the anterior cranial fossa, and if the surgeon stays caudal to this line, entrance into the anterior cranial fossa should not occur. The surgical field can be enlarged to the frontal sinus, supraorbital cells, orbit, anterior sphenoid sinus, or base of the skull; the nasofrontal duct is best opened with this approach. In an external ethmoidectomy, the anterior cells are first entered through the lamina papyracea, and then the posterior cells are progressively opened as needed. As a Lynch incision must be made, this external approach has a scar hidden in the crease of the medial orbital margin.

Internal Ethmoidectomy

The internal ethmoidectomy is an intranasal approach and usually includes resection of the middle turbinate to provide better access to the ethmoid and sphenoid cells. The ethmoid complex is usually entered via the bulla ethmoidalis; the anterior cells are resected and then the more posterior cells are opened. Although in experienced hands the lamina papyracea is not violated in this procedure, dehiscence of the lamina papyracea or a prior external ethmoidectomy is a contributing factor to inadvertant entrance into the orbit. The internal ethmoidectomy approach is used for isolated ethmoid sinus disease, for biopsies in patients who do not have coexistent antral disease, and in patients who do not wish to have an external incision.

Transantral Ethmoidectomy

The transantral approach is used when the antral cavity has coexistent sinusitis or when the intranasal approach is not possible for anatomic or technical reasons. The antrum is entered using a Caldwell-Luc approach,

FIGURE 7-63 Axial CT scans at narrow (**A**) and wide (**B**) window settings. The patient has had an osteoplastic flap procedure. The sinus is filled with fat, and the flap is clearly seen in a good position. In (**A**), the presence of the flap can be easily overlooked. Axial CT scans at narrow (**C**) and wide (**D**) window settings on another patient who has also had an osteoplastic flap procedure. The sinus is filled with fat; however, the bone flap appears elevated. This is secondary to abutting of the residual sinus septum on the flap bone and the posterior sinus wall. This will be the new normal frontal sinus appearance for this patient and demonstrates why baseline postoperative scans should be obtained.

and the medial, upper maxillary sinus wall (ethmoidomaxillary plate) is taken down so that the ethmoid cells can be entered. The ethmoid cells are then progressively resected.

In all of these ethmoidectomy procedures, the surgeon is essentially blindly cutting through the most inaccessible ethmoid septa, those located at the cranial and posterior margins of the ethmoid complex. Even when the surgeon believes that the resection extended back into the sphenoid sinus, CT often shows that the most posterior ethmoid cells and the sphenoid sinus remain untouched. Because entrance into the anterior cranial fossa is to be avoided, most surgeons favor caution and many of the most cranial ethmoid cells also remain intact. These remaining cells point out the difficulty of intraoperatively estimating one's precise anatomic position. Because disease can recur in these remaining cells, postoperative scans should be obtained if the patient's symptoms persist or recur (Figs. 7-74 to 7-84).[51, 52]

Because of the relatively small, boxlike anatomy of the ethmoid complex, postoperative hemorrhage can fill some unresected cells, and on occasion, rather than resorb, the blood becomes fibrosed or even ossified. Such en bloc fibrosis does not often occur after surgery in the other paranasal sinuses, but it is fairly common in the ethmoid complex. The imaging differentiation of recurrent disease from fibrosis can be difficult, as the attenuation values frequently are not sufficiently different to establish a definitive diagnosis. In general on CT, recurrent inflammation enhances and the fibrosis does not.

Uncommonly, a dense fibrous scar develops within the postoperative ethmoid bed. This usually has low T1-weighted and T2-weighted signal intensity and thus can be distinguished from active infection on the T2-weighted

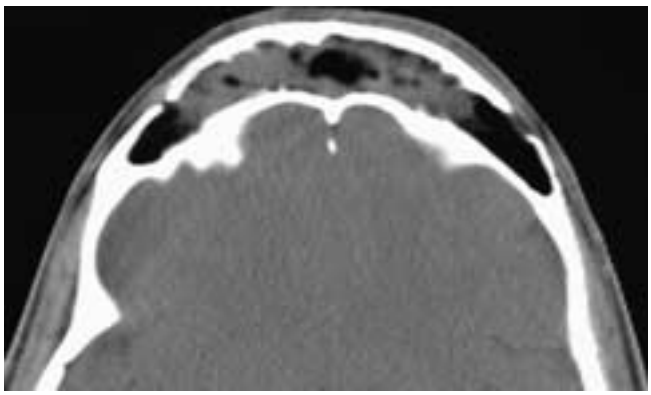

FIGURE 7-64 Axial CT scan shows an osteoplastic flap. Although over half of the fat has soft tissue rather than fat attenuation, the bone flap is in a good position and there are no inflammatory changes in the overlying soft tissues. This is a normal imaging variant of this procedure.

FIGURE 7-65 Axial CT scans at narrow (**A**) and wide (**B**) window settings. The patient has had an osteoplastic flap procedure. Despite the presence of primarily fat attenuation within the sinus, the right side of the bone flap is elevated, there is an abscess at the left margin of the flap, and there is swelling of the forehead soft tissues. This was an infected flap. Axial CT scans at narrow (**C**) and wide (**D**) window settings on another patient. In (**C**), an abscess is seen in the forehead soft tissues. Although it lies at the right margin of an osteoplastic flap, the bony flap cannot be seen clearly. In (**D**), the bony flap is clearly seen. This was an early abscess, developing after local head trauma to the region. The flap is otherwise normal on imaging.

scans. The denuded ethmoid bone may also develop a hyperostotic reaction that produces variable amounts of bone. In some cases, a localized osteoma-like bone develops; in other cases, the entire postoperative cavity may be obliterated by the bone that often mimics the appearance of fibrous dysplasia. This type of bone reaction also occurs in the maxillary sinus and to a lesser degree in the sphenoid sinus. It is rare that this reactive bone develops in the postoperative frontal sinus.

In addition to noting how extensive is the removal of the ethmoid septae, the imager should anticipate (1) an absent anterior third to half of the lamina papyracea from an

external approach, (2) an absent medial ethmoid wall and probably an absent middle turbinate from an internal approach, and (3) a Caldwell-Luc defect in the lower anterior antral wall, absent bone in the upper medial antral wall, and possibly an absent middle turbinate from a transantral approach. Any residual soft tissues in the remaining ethmoid cells should be clearly noted by the imager for future reference.

If a postethmoidectomy cavity becomes obstructed after mucosal reepithelialization, a postoperative mucocele may develop (Fig. 7-85). This mucocele usually does not grow like a typical ethmoid mucocele, which tends to expand laterally into the orbit. Rather, this postoperative mucocele takes the course of least resistance and expands within the enlarged postoperative ethmoid cavity. It is only after the entire ethmoid cavity is filled that the mucocele bulges into the orbit. On imaging, characteristically there is a collection of entrapped secretions within the postoperative ethmoid.[58]

MAXILLARY SINUS SURGERY

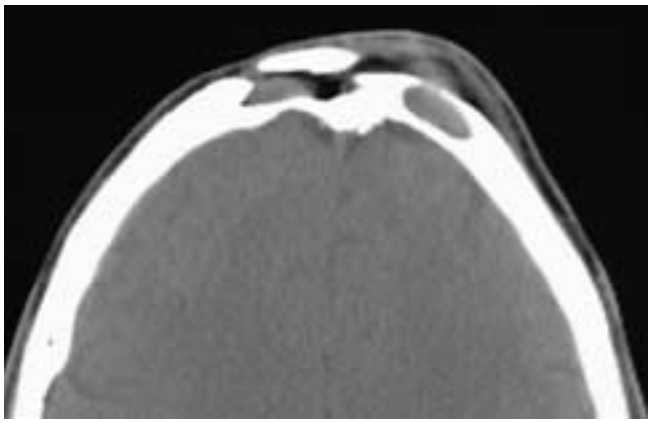
Today the most common diagnostic and therapeutic procedures performed on the antrum and the osteomeatal complex are endoscopic. However, intranasal antrostomy and the Caldwell-Luc operation are still performed. The endoscopic techniques and their postoperative appearances are discussed in Chapters 3 and 4.

Intranasal Antrostomy and the Caldwell-Luc Procedure

In an intranasal antrostomy the membranous and bony lateral nasal wall of the inferior meatus is partially resected in an attempt to create better gravity drainage for the sinus. In the Caldwell-Luc procedure, in addition to the intranasal antrostomy, the maxillary sinus is entered via the canine fossa region in the lower anterior antral wall. Because this entrance scar is intraoral, there is no facial scarring (Fig. 7-86). Once the sinus is entered, the diseased mucosa is removed. Initially the anterior wall bony defect is closed by a hematoma that eventually undergoes fibrosis (Figs. 7-87 to 7-90). However, this hematoma can uncommonly become infected, and in rare instances an oroantral fistula may be created. If this complication occurs, it is usually within the first or second postoperative week.

Via the Caldwell-Luc approach, the bone of the posterior sinus wall can also be removed to provide access for internal maxillary artery ligation or to expose the pterygopalatine fossa, vidian nerve, and pterygopalatine ganglion.[55] In such cases, a bony defect in the upper medial and posterior antral wall also can be seen on imaging.

In some patients, synechiae develop between the posterior maxillary sinus wall and the margins of the canine fossa/Caldwell-Luc defect in the anterior sinus wall. Such synechiae may form the basis for the development of a membrane that extends across the sinus between the anterior and posterior walls. Once formed, this membrane may obstruct the drainage of the lateral portion of the maxillary sinus and lead to the appearance of a postoperative antral



VIEW IMAGE

FIGURE 7-69 Axial CT scan of a patient who had a right osteoplastic flap procedure. There is an ovoid soft tissue density within the right sinus. FIGURE 7-72 Sagittal (**A**) and axial (**B**) T2-weighted MR images on a patient who has had an osteoplastic flap procedure. The right side of the obliterated sinus has a normal fat signal intensity. However, the middle and left regions of the sinus have high signal intensity. This usually indicates the presence of infection, but this patient was asymptomatic. Such high T2-weighted signal intensity may be a normal postoperative MR finding. There is no elevation of the bone flap, and there are no inflammatory changes in the forehead soft tissues.

mucocele. In these cases, the medial postoperative sinus cavity remains aerated, while the lateral sinus cavity first becomes obstructed and then, as a mucocele develops, expanded. The imaging appearance of a laterally expanded mucoid mass in such a sinus signifies the presence of a postoperative mucocele (Figs. 7-91 and 7-92). Less often, postoperative antral mucoceles can occur in the maxillary recesses in the tuberosity and in the hard palate.

As previously mentioned, once the sinus mucosa has been stripped from the sinus wall, a bony reaction may be elicited that results in reactive bone formation, thickening of the sinus wall, and reduction or obliteration of the sinus cavity. Such a reaction is an expected consequence of the procedure and should not necessarily signify to the radiologist that active infection is present (Figs. 7-88 and 7-89).[59]

However, in (**B**), the left ethmoid septa and the anterior sphenoid sinus wall are intact, indicating that no surgery was performed. In order to avoid such mistakes, these cases should always be viewed at wide window settings.

patients with thyroid ophthalmopathy may be treated by surgical decompression of the orbit. The procedures most commonly employed are a lateral orbitotomy (Krönlein's procedure); an antral (orbital floor) decompression using a Caldwell-Luc approach; an ethmoid decompression using an external ethmoidectomy approach; and an orbital roof decompression accomplished via a craniotomy. Of these operations, the greatest degree of decompression from a single procedure is obtained from the orbital floor approach. However, this procedure must be performed bilaterally so that the visual axes are not made asymmetric, resulting in diplopia and cosmetic deformity. The lateral and ethmoid decompressions can be combined with antral decompressions to achieve maximal relief of exophthalmos and a decrease in intraorbital pressure. The orbital roof approach provides relatively little decompression, and because it is a

If this septum completely obstructs the lateral portion of the sinus, a postoperative mucocele will develop.

more extensive surgical approach, it is reserved for the most severe cases.

On sectional imaging, the absence of the lateral portion of the orbital wall may at first elude detection, the imager's attention being drawn by pronounced proptosis with muscle enlargement. However, careful evaluation of the bony orbital walls will show that a Krönlein procedure was performed (Figs. 7-93 and 7-94). The ethmoid decompression has the same appearance as an external ethmoidectomy, and it is the orbital muscle findings of thyroid ophthalmopathy that suggest the diagnosis (Figs. 7-93 to 7-95). The antral decompression reveals prolapse of the orbital fat and inferior muscles into the upper maxillary sinuses. Without a history, on axial scans this operation may present a confusing picture, often mimicking unusual antral disease. However, coronal scans reveal that most of the orbital floor bone is missing, a finding that differentiates this postoperative appearance from the rare event of bilateral orbital floor blow-out fractures, in which the displaced fracture's segments can be identified (Figs. 7-94 and 7-96).

SPHENOID SINUS SURGERY

The sphenoid sinuses can be approached through the anterior sinus wall for biopsy, to improve sinus drainage, or to remove inflammatory tissue. The sphenoid sinusotomy opens the anterior wall of the sinus and creates a wide-open cavity that leads into the nasopharynx (Fig. 7-97). The sinus can be reached by intranasal, transseptal, transmaxillary, or transethmoidal approaches.

In the transnasal approach, portions of the posterior middle turbinate, the superior turbinate, and some of the posterior ethmoid cells are removed to gain exposure. In the transseptal approach, portions of the cartilaginous and bony nasal septum (vomer) are removed. The transmaxillary

approach is an extension of a Caldwell-Luc procedure in which a transmaxillary ethmoidectomy is extended to include the anterior sphenoid sinus wall. The transethmoidal approach is simply a posterior extension of an external ethmoidectomy procedure. Thus, depending on the approach used, in addition to a widened ostium or an absence of one or both anterior sphenoid sinus walls, the respective surgical defects just described should be observed on images.[55, 56]

When a sphenoid sinusotomy is performed, care must be taken to avoid trauma to the carotid artery. In 17% of patients the bony wall separating the sinus and artery is so thin that it provides little if any protection from trauma, and carotid artery damage may lead to a posttraumatic aneurysm or a carotid-cavernous fistula.[60, 61] Similarly, damage can occur to the cavernous sinus and to the vidian, maxillary, and optic nerves in those patients who have these nerves running within the sinus (see Chapters 2 and 3).

A transsphenoidal hypophysectomy can be performed as an extension of a sphenoid sinusotomy. Once the sphenoid sinus cavity is surgically exposed, portions of the anterior wall and the floor of the sella turcica can be removed and the pituitary fossa entered from below. Muscle, fat, cartilage, or bone may be used to seal the surgical defect. On sectional imaging, in addition to the site of surgical bone removal, sclerotic thickening of the remaining portions of the anterior wall and the floor of the sella turcica may be observed. Some postoperative prolapse of sellar contents, including fat, into the sphenoid sinus can occur, and without benefit of the surgical history, the imaging picture can simulate that of a large pituitary tumor with extension into the sphenoid sinus.

In the preoperative evaluation of patients being considered for a transsphenoidal hypophysectomy, the imager must direct special attention to the thickness of the bone forming the anterior wall of the sella turcica. In nearly 99% of patients, the sphenoid sinus development extends back to within 1 mm of the anterior wall or under the sellar floor. However, in the 1% of patients in whom a thick margin of bone remains between the sinus and sella, the transsphenoi-

dal approach is not desirable; instead, an intracranial approach is used often.[31]

SURGERY FOR SINUS MALIGNANCY

The type of tumor-curative operation performed on the maxillary sinus varies, depending upon the precise location of the primary neoplasm. Thus a tumor affecting the lower portion of the antrum may require an infrastructure-type partial maxillectomy, while a nasal tumor may require a medial maxillectomy. More extensive tumor necessitates a total maxillectomy with or without removal of the pterygoid plates and adjacent structures. A partial or total ethmoidectomy is often combined with a maxillectomy for complete tumor extirpation.

Medial Maxillectomy

For localized nasal tumors that only involve a portion of the medial antral wall, a partial or medial maxillectomy is performed, usually in association with a partial ethmoidectomy and a resection of the nasal tumor. If the lower antral wall is involved, portions of the adjacent hard palate and maxillary alveolus may also be included in the resection (Fig. 7-98). Thus, in a partial maxillectomy, the medial antral wall, the inferior turbinate, often the middle turbinate, the lower ethmoid cells, and, if appropriate, portions of the hard palate and alveolus are removed. The lateral portion of the antrum and its mucosa remain intact.

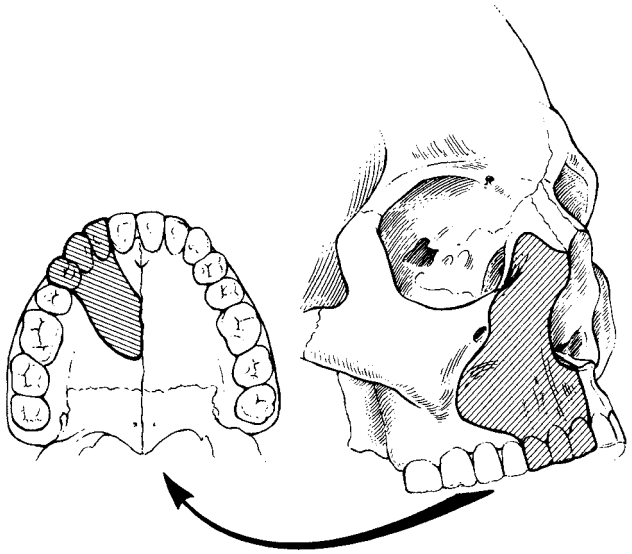

FIGURE 7-98 Diagram of a typical medial maxillectomy resection. A portion of the palate is removed if needed to obtain a tumor-free margin. The medial antral wall and inferior turbinate are also included in the resection.

VIEW IMAGE

FIGURE 7-99 Diagram of a typical total maxillectomy resection. Variable portions of the zygoma and pterygoid plates may be included in the resection. Similarly, the orbital floor may be taken in its entirety, and an ethmoid resection (*dotted line*) may also be included to obtain a tumor-free margin.

Total Maxillectomy

For more extensive tumors, a total maxillectomy is performed (Fig. 7-99). In addition to resection of the maxilla, there is some variation as to what is included in the resection. Such surgery may include the body of the zygoma, the ipsilateral hard palate and alveolus, the inferior turbinate, and often the pterygoid plates and portions of the ethmoid sinuses.[62, 63] Modifications are made to fit the specific tumor location. Thus the orbital floor may be left in place or it may be included along with an orbital exenteration. The latter is performed when there is gross tumor extension into the orbit.

Erosion of the bones lining the orbit may necessitate an orbital exenteration, and the degree of orbital involvement must be noted by the imager in order to aid the clinician in planning surgery. Gross orbital invasion almost always requires an orbital exenteration. However, erosion of bone, without gross penetration of the periorbita, may or may not necessitate an orbital exenteration. To some degree, this depends on the particular philosophy of the clinician and the tumor histology.

Today, there is a tendency not to exenterate an orbit for minimal disease, especially if the periorbita remains intact. This is a less aggressive approach than that of several decades ago, when exenteration was almost always performed. This is due in part to better chemo/radiation treatments and in part to a change in philosophy based on statistics noting tumor recurrences.

For squamous cell carcinoma, the initial involvement of any orbital bone must be considered when surgery is performed, even if preoperative chemo/radiation has shrunk the tumor away from the orbit. Failure to do so usually results in an orbital margin recurrence. With other tumors such as olfactory neuroblastomas, initial involvement of the orbital wall need not result in an exenteration. If there is a good preoperative tumor response to chemo/radiation and the orbit becomes grossly free of tumor, in most cases tumor resection without an exenteration may be curative.

After the bone is resected, the postmaxillectomy cavity can be lined with a split-thickness skin graft to create an immediate epithelial surface, or a muscle graft can be placed to fill the cavity. If the orbital floor was removed, various synthetic grafts can be placed to help support the orbital contents. Similarly, bone and prosthetic material can be placed to support the anterior and lateral facial structure, and prostheses can be placed to fill the surgical defects created in the hard palate and alveolus. These foreign substances can cause imaging problems either because they may degrade the image quality or because, in the case of some plastics and musculofascial grafts, on MR imaging they may simulate normal bone and go undetected. Eye prostheses also may cause degradation artifacts on scans.

As mentioned, there is a tendency today to obliterate the postoperative maxillectomy cavity created, with or without an ethmoidectomy, by using a rotated myocutaneous graft. Such a graft brings muscle, fat, and soft tissues into an area in which they normally are not present, and recognition of such a graft will obviate difficulties in interpreting postoperative CT and MR images.

The sinus cavity in a partial maxillectomy patient is lined by normal mucosa. The defect after a total maxillectomy can be lined either by a split-thickness skin graft or a myocutaneous graft. In any case, after a 6- to 8-week postoperative interval, nearly all of the operative-related edema and hemorrhage will have subsided and a baseline scan should be performed. This scan maps the patient's new anatomy and establishes the contour and thickness of the postoperative mucosal surfaces. The normal postoperative mucosa is smooth and moderately thin. Any localized area of soft-tissue nodularity or mucosal-submucosal thickening must be suspected of representing recurrent tumor until proven otherwise. If such an area develops that was not noted on the baseline scan, the imager should direct the clinician specifically to this site for biopsy (Figs. 7-100 to 7-109). This approach has led to more positive biopsy specimens than are obtained from clinical assessment alone. The routine postoperative imaging follow-up of patients has also led to identification of small, early recurrences that were overlooked on routine clinical follow-up.[62]

EXTENSIVE NASOETHMOID SURGERY

The lateral rhinotomy provides access to the entire nasal cavity and the maxillary, ethmoid, and sphenoid sinuses. Modifications and extensions of this approach can be used to include access to the frontal sinuses. The typical incision extends from just below the medial end of one eyebrow, caudally between the nasal dorsum and medial canthus of the eye, down the nasofacial crease, and along the nasal alar rim. The incision is then extended down the upper lip if necessary. The nose is turned to the side, thereby exposing the pyriform aperture. This procedure gives access to the entire lateral nasal wall and nasal septum. Usually removed

at surgery are the medial antral wall, the ethmoid cells, and the inferior and middle turbinates. The anterior sphenoid wall can be resected via this procedure, and the operation can be extended to include the entire nasal septum and contralateral nasal cavity structures, resulting in a total rhinotomy. In general, the operation of choice for a unilateral nasal tumor is a medial maxillectomy with a lateral rhinotomy and ethmoidectomy. Despite the extent of the resection, the cosmetic and functional results are excellent. Regarding patient follow-up, as with the postmaxillectomy patient, the same general imaging rules apply, namely, one must suspect tumor at sites of soft-tissue nodularity and mucosal thickening (Figs. 7-110 to 7-113).

CRANIOFACIAL RESECTION

This large operation is reserved for patients with tumors of the superior nasal cavity, ethmoid sinuses, frontal sinuses, anterior sphenoid sinuses, and orbits. The operation essentially combines a frontal craniotomy with a resection of the

FIGURE 7-112 Coronal CT scan on a patient after an extended right lateral rhinotomy. The floor and medial wall of the right orbit have been removed. Although the thickened soft tissues along the orbital margin could be either scar or recurrent tumor, the smooth margin suggests that tumor is not present. The best way to evaluate this disease is to compare this scan with a previous study. Biopsy may be necessary. No tumor was present in this patient.

midportion of the floor of the anterior cranial fossa and an extended lateral rhinotomy. The surgery is often performed by a skull-base team comprised of a neurosurgeon and an otolaryngologist. Initially, one of several types of frontal or bifrontal craniotomies is performed, the frontal lobes are elevated, and any tumor extension into the brain is resected. The bone and dura in the floor of the anterior cranial fossa are then incised. The typical resection includes the posterior wall of the frontal sinuses, the cribriform plate, the fovea ethmoidalis on each side, and as much of the medial orbital roof as is necessary to obtain a margin around the tumor. The posterior incision runs along the posterior roof of the sphenoid sinus, and it can extend back to the tuberculum sella. An extended lateral rhinotomy is then performed, and the resection includes one or both ethmoid sinuses (including the corresponding medial orbital wall), the nasal septum, and if necessary a portion of the medial maxilla. Once the entire specimen is free, the surgeons proceed with an en bloc extirpation. An anterior dural flap and a temporalis free musculofascial graft are used to close and support the cranial floor defect, and the lateral rhinotomy is closed separately (Fig. 7-114).[51, 64, 65]

Postoperative CT scans contain several areas that may cause diagnostic difficulties. First, the anterior dura adjacent to the frontal osteotomy becomes thickened and enhances on contrast studies. This appearance may persist indefinitely and relates to a low-grade reactive process that obliterates the dural spaces (Fig. 7-115). Second, the musculofascial flap that supports the central region of the floor of the anterior cranial fossa can bulge slightly downward into the upper postoperative nasoethmoid cavity (Figs. 7-116 and 7-117). This can simulate a tumor mass on axial CT scans and MR images, but usually can be identified as representing the graft region on coronal studies. This is especially true during the period before the free flap becomes completely fibrosed, usually between 2 and 8 months after the surgery. Although the CT appearance is not effectively altered once the flap is completely fibrosed, the MR imaging findings are changed. The initial intermediate T1-weighted and high T2-weighted signal intensities are gradually replaced by low signal intensities or signal voids on all imaging sequences. This change corresponds to replacement of the graft by scar. The thickness of the fibrosed graft may occasionally be sufficiently similar to that of the remaining bony floor of the adjacent anterior cranial fossa that on coronal MR images the radiologist may not detect that bone has been removed (Fig. 7-118). Only the altered contour of the bony floor of the anterior cranial fossa (absent the crista galli and fovea ethmoidalis) may signify that the surgery included the bone in this region. Such bone defects are seen easily on coronal CT. There are slight variations in the imaging appearance of patients who have had craniofacial procedures, primarily reflecting variations in the surgical approach (Figs. 7-119 and 7-120).

Any nodularity along the cranial or nasal margin of the graft or postoperative sinonasal cavity must be suspected of

Speckled calcifications are seen within each tumor nodule. This patient had recurrent adenocarcinoma.

representing tumor. Progressive thickening of the graft or an upward convexity along the cranial margin of the graft are possible signs of tumor recurrence. Unfortunately, a vascularized scar tissue develops postoperatively that has imaging findings similar to those of recurrent tumor on both CT and MR imaging, with or without contrast. However, this tissue will not progressively grow on serial imaging studies. Thus, tumor recurrence in these patients is best detected by a change in the mucosal or graft surface contour or thickness.[51] Occasionally, inflammatory disease including abscess formation may be seen after surgery. However, in these cases, the clinical presentation usually suggests the diagnosis (Figs. 7-121 to 7-124).

Although technically large graft replacements of the facial area can be performed, the cure rate of such major surgery is often disappointing. Tumor recurrences can occur either deep within the graft or adjacent to the surgical bed (Figs. 7-125 and 7-126).

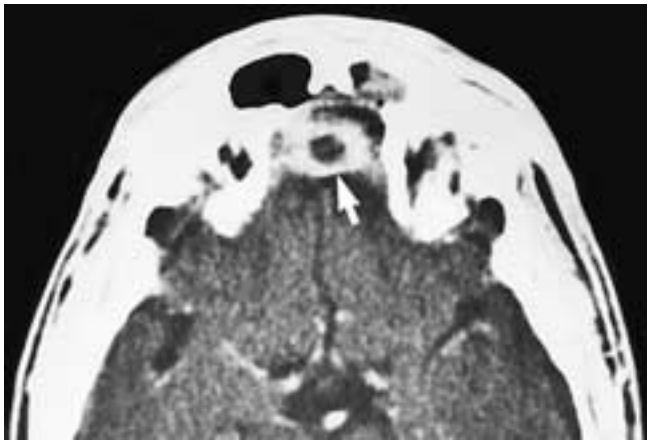

FIGURE 7-124 Axial contrast-enhanced CT scan shows a ring-enhancing mass (*arrow*) just cranial to the fascial-muscle graft in a patient who has had a craniofacial resection. This patient had a postoperative abscess.

EMBRYOLOGY OF THE EYE

The globe is formed from the neuroectoderm of the forebrain, the surface ectoderm from the head, the mesoderm lying between these layers, and neural crest cells.[1] The neural tube ectoderm (neuroectoderm) gives rise to the retina, the fibers of the optic nerve, and the smooth muscles (the sphincter and dilator papillae) of the iris.[1] The surface ectoderm on the side of the head forms the corneal and conjunctival epithelium, the lens, and the lacrimal and tarsal glands.[1, 2] Although the mesenchymal cells are derived from mesenchyme, neural crest cells also migrate into this mesenchyme, and it is from this combined mesenchyme that the corneal stroma, the sclera, the choroid, the iris, the ciliary musculature, part of the vitreous body, and the cells lining the anterior chamber are formed.[2]

The rudimentary eyes appear as two neuroectodermally lined hollow diverticula (grooves) extending from the lateral aspects of the forebrain (diencephalon) (Fig. 8-1). It is in the third week of gestation (22 days) that these diverticulae appear, one on either side of the neural groove. These are the optic pits, and they deepen to form the optic vesicles, which can be identified in the 4 mm embryo (less than 4 weeks of gestation)[3] (Fig. 8-1). The diverticula grow out laterally, and their ends come into close apposition with the overlying surface ectoderm. The apposition of the outer wall of each optic vesicle to the overlying surface epithelium is essential for the transmission of inductive messages that stimulate the surface ectoderm to form a small area overlying the optic vesicle that thickens and forms the lens placode. As the process of lens induction proceeds, the outer surface of the optic vesicle flattens and then becomes concave toward

the surface of the embryo. This results in the transformation of the distal end of the optic vesicle into the double-layered optic cup. The proximal portion of each optic vesicle becomes constricted to form the optic stalk[1–6] (Figs. 8-1 and 8-2). The lens placode invaginates and sinks below the surface ectoderm to become the lens pit, and its edges come together and fuse to enclose a hollow lens vesicle[1–6] (Figs. 8-2 and 8-3). By the fifth week, the lens vesicle loses contact with the surface ectoderm and lies within the mouth of the optic cup, the edges of which form the future pupil[1–7] (Figs. 8-1 and 8-3). The lens vesicle initiates a new series of inductive reactions by acting on the overlying surface ectoderm to begin development of the cornea.

In the 5 mm embryo, the invagination is not limited to the outer wall of the optic vesicle, but also involves its caudal surface and extends in the form of a groove for some distance along the optic stalk[2] (Figs. 8-1 and 8-2). Thus, for a time, a wide hiatus, the optic fissure or choroidal fissure (embryonic fissure), exists in the inferior edge of the optic cup.[1, 2] The embryonic fissure remains open for some distance along the optic stalk at the inferior and slightly nasal aspect of the optic cup (Figs. 8-1 and 8-2). Through the embryonic fissure, the mesenchyme extends into the optic stalk and cup, carrying the hyaloid artery with it to the posterior surface of the lens[1–3] (Fig. 8-3). The hyaloid artery, a branch of the ophthalmic artery, supplies the inner layer of the optic cup, the lens vesicle, and the mesenchyme in the optic cup (Figs. 8-4 and 8-5). The hyaloid vein drains blood from these structures. Later, as growth proceeds, the edges of this fissure become narrowed, and by the seventh week of embryonic development the fissure closes, forming a narrow tube, the optic canal, inside the optic stalks. Failure of the choroidal fissure to close completely results in a coloboma (a notched defect) formation, which may include the iris, ciliary body, choroid, retina, or optic nerve.

The retina develops from the optic cup (Figs. 8-2 and 8-3). For purposes of description, the retina may be divided into two developmental layers, the pigment layer and the neural layer. Its two layers are at first equipotential and mutually interchangeable. The pigment layer is formed from the outer thinner layer of the optic cup. It is a single layer of cells that becomes columnar in shape, and pigment granules develop within the cytoplasm of these cells. The neural layer is formed from the inner layer of the optic cup.[1–6] It is

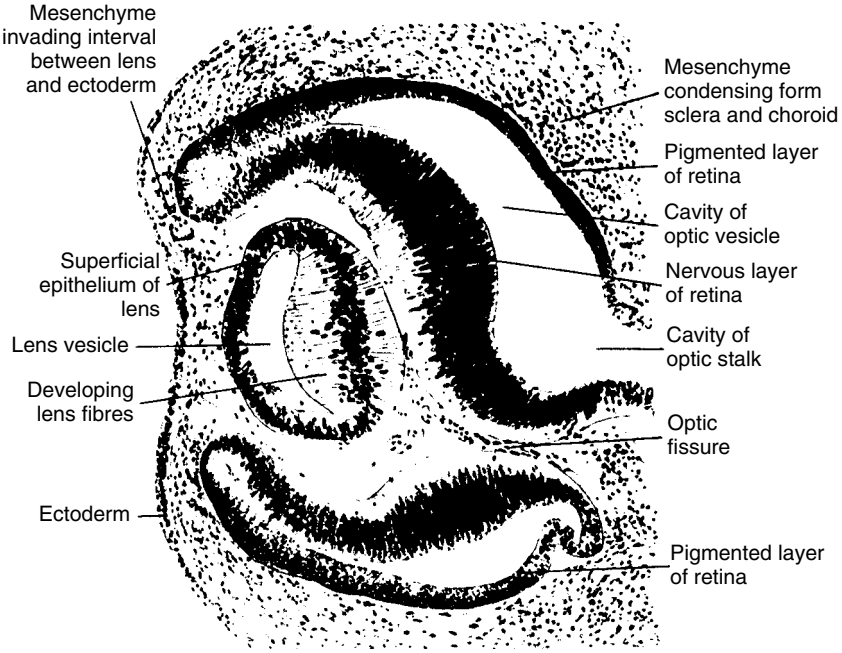

FIGURE 8-3 A lateral section through the developing eye of a human embryo 13.2 mm long. (From Bannister LH, Berry MM, Collins P, Dyson M, et al. (eds). Gray's Anatomy, 38th ed. Edinburgh: Churchill Livingstone, 1999; 259.)

important to realize that in the region of the cup that overlaps the lens, the inner layer is not differentiated into neural elements. This anterior one-fifth of the inner layer persists as a layer of columnar epithelium, which, together with the corresponding part of the pigmented epithelium of the outer layer, extend forward onto the posterior surface of the developing ciliary body and iris to form the double epithelium of the ciliary body and iris.[1, 2] The posterior four-fifths of the inner layer of the optic cup undergoes cellular proliferation, forming an outer nuclear zone and an inner marginal zone devoid of nuclei (Fig. 8-3). Later, at the 12 mm stage, the cells of the nuclear zone invade the marginal zone, so that at the 17 mm stage, the neural part of the retina consists of an inner and an outer neuroblastic

Copyright © 2003, Mosby, Inc. All rights reserved.

layer.[2] The inner neuroblastic layer of the retina forms the ganglion cells, the amacrine cells, and the somata of the sustentacular fibers of Müller.[1, 2, 8, 9] The outer neuroblastic layer of the retina gives rise to the horizontal cells, the nuclei of the bipolar rod and cone nerve cells, and probably the rod and cone cells as well (Fig. 8-6).[1, 2]

By the eighth month of fetal life, all the layers of the retina can be recognized[1, 2] (Fig. 8-7). Thus, the inner layer of the optic cup may be divided into a small nonneural portion near the edge of the cup and a large photosensitive portion, the two being separated by a wavy line, the ora serrata. It is interesting to remember that the cavity of the optic vesicle is continuous through the optic stalk (optic canal) with the cavity of the diencephalon (i.e., the part that forms the third ventricle) (Figs. 8-1 and 8-2). Early in development, the outermost layer of cells of the nuclear zone have cilia, which are continuous with the ciliated ependymal cells of the third ventricle.[2] Later, during the seventh week of development, the cilia of the cells of the nuclear zone disappear and are believed to be replaced by the outer segments of the rods and cones during the fourth month of gestation.[2]

Optic Nerves, Macular Area, and Fovea Centralis

The deepest part of the optic (embryonic) fissure is at the center of the floor of the optic cup[1] (Figs. 8-1 and 8-2). In this region, which later is the site of the optic disc, the inner (neural) cell layer of the cup is continuous with the corresponding invaginated cell layer of the optic stalk (Fig. 8-3). As a result, the developing nerve fibers of the ganglion cells can pass directly into the wall of the stalk to become the optic nerve.[1] At the 7.5 mm embryonic stage, the area in the optic cup where the optic nerve head will develop can be identified.[5] It is referred to as the primitive epithelial papilla and is located at the superior end of the embryonic fissure.[10] Once the axons pass through the primitive epithelial papilla, it is referred to as the optic nerve head.[5, 10, 11]

The macular area first develops as a localized increase of superimposed nuclei in the ganglion cell layer, lateral to the optic disc, just after midterm. During the seventh month there is a peripheral displacement of the ganglion cells, leaving a central shallow depression, the fovea centralis. The foveal cones decrease in width in their inner segments, but

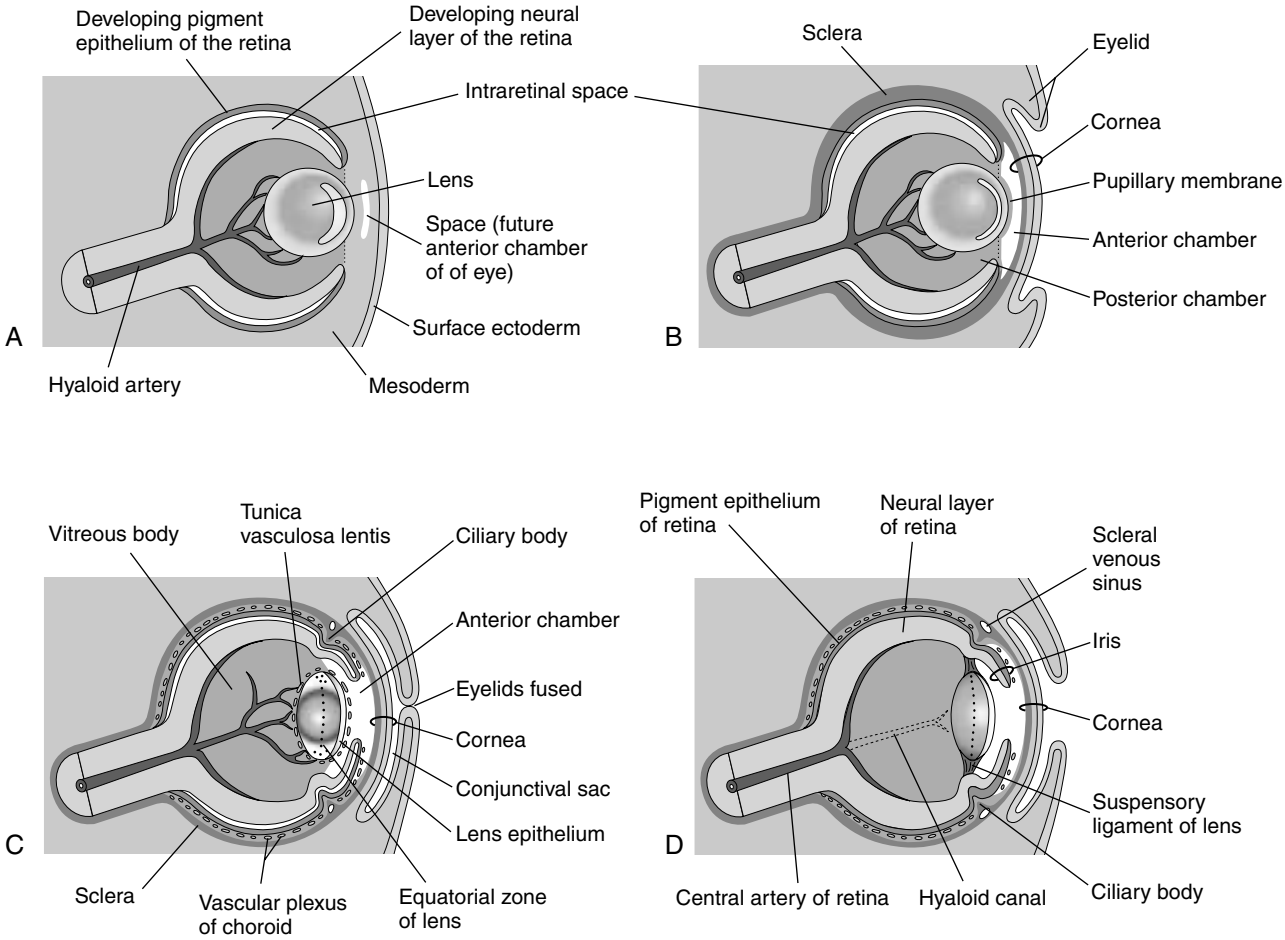

FIGURE 8-5 Drawings of sagittal sections of the eye showing successive developmental stages of the lens, retina, iris, and cornea. **A**, 5 weeks; **B**, 6 weeks; **C**, 20 weeks; **D**, newborn. Note that the layers of the optic cup fuse to form the retinal pigment epithelium and neural retina and extend anteriorly as the double epithelium of the ciliary body and its iris. The retina and optic nerve are formed from the optic cup and stalk (outgrowths of the brain). At birth the eye is about three quarters of its adult size. Most successive growth occurs during the first year of life. (From Moore KL, Persaud TVN. The Developing Human: Clinically Oriented Embryology 6th ed. Philadelphia, Pa: Saunders, 1998; 498.)

FIGURE 8-6 Drawing of the tissue and cellular organization of the neural retina of the human fetus. **A**, Amacrine cell; **B**, bipolar cell; **C**, cone, **G**, ganglion cell; **H**, horizontal cell. **R**, Rod. (From Carlson BM. Human Embryology and Developmental Biology, 2nd ed. St. Louis, Mo: Mosby, 1994; 271.)

their outer segments are elongated. This permits an increase in foveal cone density.[2] At birth, the ganglion cells have been reduced to a single layer in the fovea, and by 4 months of age, the cone nuclei in the center of the fovea have no ganglion cells covering them. The reason for the newborn's imperfect central fixation is that the cones do not fully develop until several months after birth.[2]

The ganglion cells of the retina develop axons that converge to a point where the optic stalk leaves the posterior surface of the optic cup (Fig. 8-3). This site will later become the optic disc.[1–3, 9] The axons now pass among the cells that form the inner layer of the stalk. Gradually, the inner layer encroaches on the cavity of the stalk until the inner and outer layers fuse. The cells of the optic stalk form neuroglia-supporting cells to the axons, and the cavity of the stalk disappears. The stalk, together with the optic axons, forms the optic nerve. The surrounding mesenchyme condenses and later differentiates into the meninges, which form a sheath for the optic nerve. The axons of the optic nerve begin to develop their myelin sheaths just before birth, but the process of myelination continues for some time after birth.[1–3] After the eyes have been exposed to light for about 10 weeks, myelination is complete. The hyaloid artery and vein become the central artery and vein of the retina, running for a distance within and along the optic nerve.[1, 2]

Lens

As described, the rudimentary lens is first seen as a thickening of the surface ectoderm, the lens placodes, at 22 days of gestation; it overlies the optic vesicle (Figs. 8-1 and 8-2). The lens placode invaginates and sinks below the surface ectoderm to form the lens vesicle, which is overlapped by the margin of the optic cup and becomes separated from the overlying ectoderm by mesenchyme.[1, 2] The cells forming the posterior wall of the lens vesicle rapidly elongate and form transparent lens fibers known as the primary lens fibers (Fig. 8-3). At the cellular level, the relatively unspecialized lens epithelial cells undergo a

profound transformation into transparent, elongated cells that contain large quantities of crystallin proteins, the primarily proteins being α, β, and γ.[12] With the increase in length of these cells, the cavity of the lens vesicle gradually becomes obliterated.[2] The primary lens fibers become attached to the apical surface of the anterior lens epithelium.[2] All additional lens fibers are formed by the division of the anterior epithelial cells at the equatorial zone or rim of the lens (Figs. 8-8 and 8-9). These are known as the secondary lens fibers, and new secondary lens fibers are formed throughout life.

By the second month of gestation, the lens is invested by a vascular mesenchymal condensation termed the *vascular capsule of the lens*, the ventral part of which, covering the lens, is named the pupillary membrane. The blood vessels supplying the dorsal part of this capsule are derived from the hyaloid artery, and those for the ventral part are derived from the anterior ciliary arteries.[1, 2] By the sixth month, all the vessels of the capsule are atrophied except the hyaloid artery, which becomes occluded during the eighth month of gestation.[1, 2] With the loss of its blood vessels the vascular capsule of the lens disappears (Fig. 8-4, 8-5), but sometimes the pupillary membrane persists at birth, giving rise to the condition termed *congenital atresia of the pupil*.[1, 2] In the fetus the lens grows rapidly because it is supplied by the hyaloid artery, which forms a plexus on the posterior surface of the lens capsule. By the time the infant is born, the anteroposterior diameter of the lens is nearly that of an adult. Its equatorial diameter is about two-thirds of that reached in the adult.[2]

The lens capsule is formed from the mesenchyme that surrounds the lens. As mentioned, in the earliest stages of development, it receives an abundant arterial supply from the hyaloid artery as the tunica vasculosa lentis. Later, this blood supply regresses, and it disappears before birth. In the 40 mm human embryo, the layers of the retina, developing lens, pupillary membrane, cornea, conjunctival sac, anterior and posterior aqueous chambers, the developing vitreous body, the condensing circumoptic mesenchyme, and the fused eyelids are recognized (Fig. 8-7).[1]

Throughout most of its life, the lens is under the influence of the retina. Thus, following induction of the lens, chemical secretions from the retina accumulate in the vitreous humor behind the lens and appear to stimulate the formation of lens fibers.[12]

The Ciliary Body and Suspensory Ligaments of the Lens

The mesenchyme, situated at the edge of the optic cup, differentiates into the connective tissue of the ciliary body,

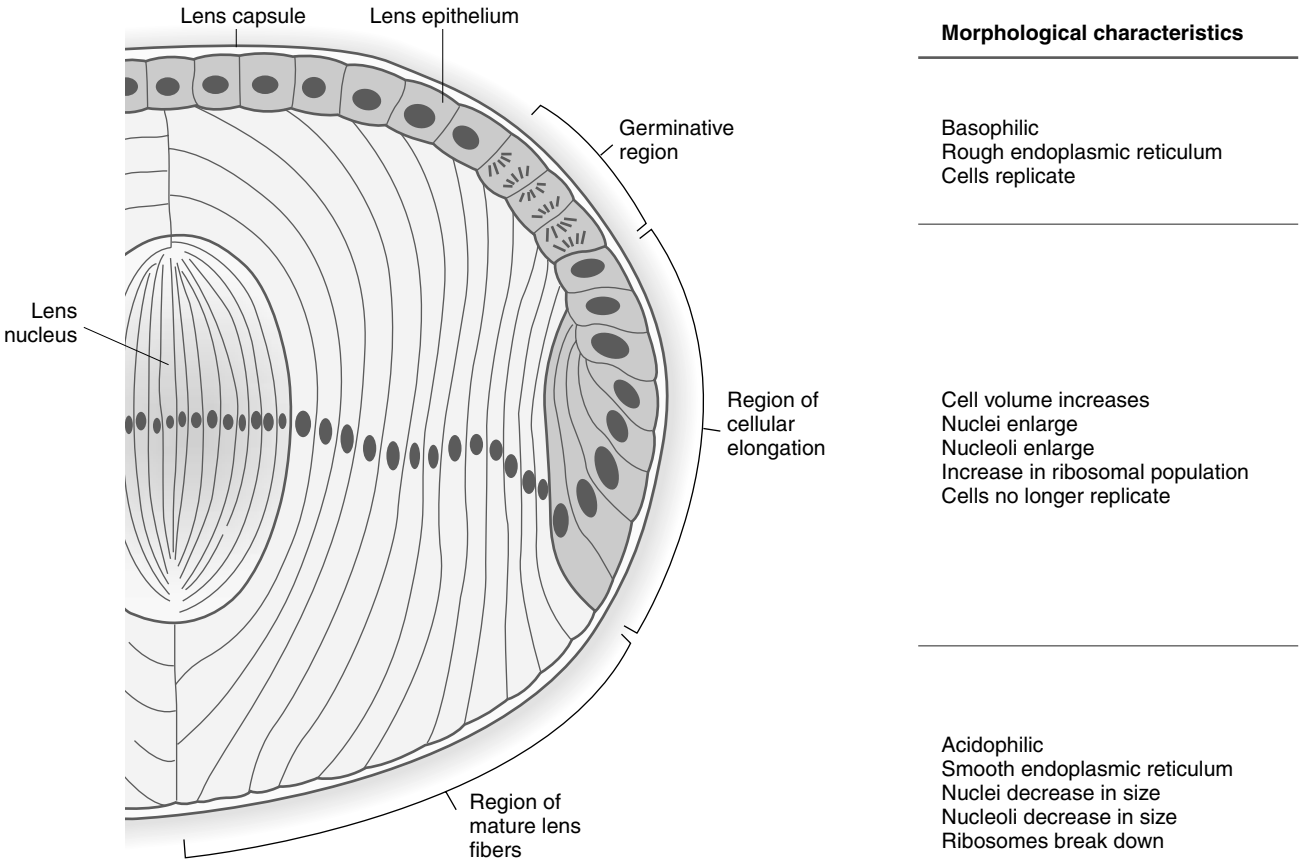

FIGURE 8-8 Drawing of the organization of the vertebrate lens. As the lens grows, epithelial cells from the germinative region stop dividing, elongate, and differentiate into lens cells that produce lens crystallin proteins. (Papaconstantinou J. Molecular aspects of lens cell differentiation. Science 156:338–346, 1967.)

(From Moore KL, Persaud TVN, Shiotak: Color Atlas of Clinical Embryology. Philadelphia, WB Saunders, 1994.)

the smooth muscle fibers of the ciliary muscle, and the suspensory ligaments of the lens. The two layers of neuroectoderm (the outer pigment layer and the anterior one-fifth of the inner layer) forming the edge of the optic cup grow onto the posterior surface of the ciliary muscle, forming the two epithelial layers covering the ciliary body.[2] The fibers of the ciliary muscles are derived from the mesoderm, but those of the sphincter and dilator pupillae are of ectodermal origin, being developed from the cells of the pupillary part of the optic cup (Fig. 8-10).[1, 2]

The Iris and the Aqueous Chamber

The mesenchyme, situated on the anterior surface of the lens, condenses to form the pupillary membrane. The two layers of neuroectoderm (the pigment layer of the retina and the neural layer of the retina) forming the growing edge of the optic cup, having covered the ciliary muscle, now extend onto the posterior surface of the pupillary membrane. These structures fuse to become the iris.[2] The sphincter and dilator muscles of the pupil are derived from the pigment cells of the neuroectoderm. The mesenchyme forms the connective tissue and blood vessels of the iris. Pigment cells derived from the neuroectoderm penetrate the sphincter muscle and enter the connective tissue. The opening in the central part of the iris becomes the pupil. The pupillary membrane begins to separate from the iris, and at about the eighth month of gestation, the pupillary membrane starts to degenerate and eventually disappears.[2]

The anterior (aqueous) chamber of the eye appears as a cleft in the mesenchyme between the surface ectoderm and the developing iris.[1, 2] The posterior chamber develops as a slit in the mesenchyme posterior to the developing iris and anterior to the developing lens (Fig. 8-5). The mesenchyme superficial to the cleft forms the substantia propria of the cornea. The mesenchyme deep to the cleft forms the mesenchymal stroma of the iris and the pupillary membrane (Fig. 8-10).[1] When the pupillary membrane disappears, the anterior and posterior chambers of the eye communicate with each other through a circumferential scleral venous sinus (sinus venosus sclerae, canal of Schlemm).[1] This sinus (canal) is the outflow site of aqueous humor from the anterior chamber of the eye to the venous system. Temporally, the anterior and posterior chambers communicate when the pupillary membrane disappears and the pupil is formed.[1]

The Vitreous

The vitreous body develops between the developing lens and the optic cup. The primitive or primary vitreous body consists of a network of delicate cytoplasmic processes that

Copyright © 2003, Mosby, Inc. All rights reserved.

are derived partly from the ectodermal cells of the developing lens and partly from the neuroectoderm of the retinal layer of the optic cup. The mesenchyme that enters the cup through the choroidal (embryonic or optic) fissure and around the equator of the lens becomes intimately united with this reticular tissue and also contributes to the formation of the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm.[1, 2] It contains many vascular elements, including the vasa hyaloidea propria, which join the primitive vitreous. At this stage, the primitive vitreous is supplied by the hyaloid artery and its branches. The definitive or secondary vitreous arises between the primitive vitreous and the retina. It is at first a homogeneous gel, which rapidly increases in volume and pushes the primitive vitreous anteriorly behind the iris. Hyalocytes, derived from the mesenchyme around the hyaloid vessels, now migrate into the secondary vitreous. Later the hyaloid vessels atrophy and disappear, leaving the acellular hyaloid canal.[2] The hyaloid artery becomes occluded during the eighth month of intrauterine life.[2] Prior to this, during the fourth month, the hyaloid artery gives off retinal branches, and its proximal part persists in the adult as the central artery of the retina.[2] The hyaloid canal, which carries the artery through the vitreous during development of the primitive (primary) vitreous, persists after the vessel has become occluded.[1, 13–15]

The Choroid

Outside the optic cup, there is a layer of mesenchymal cells that are primarily of neural crest origin. As a result of induction from the pigmented epithelium of the retina, these mesenchymal cells differentiate into structures that provide the vascular and mechanical support of the eye.[12] The innermost cells of this mesenchymal layer become the highly vascular choroid, and the anterior part of the choroid is eventually modified to form the ciliary body and ciliary processes.

The Sclera

The sclera is also derived from the mesenchyme surrounding the optic cup, outside the choroid. This mesenchyme forms a densely collagenous covering, the sclera, which is continuous with the cornea. It first forms near the future insertion of the rectus muscle.[1]

The Cornea

The formation of the cornea is the last in the series of inductive events in the formation of the eye. Corneal development is induced by the lens and the optic cup.[1] The corneal epithelium is formed from the surface ectoderm and the mesothelium of the anterior chamber from the mesenchyme[2] (Figs. 8-5, 8-9). The substantia propria and the endothelium covering the posterior surface of the cornea are formed from mesenchyme.[1] Bowman's membrane, which lies immediately beneath the basal lamina of the corneal epithelium, is formed from mesenchyme.[1] Descemet's membrane, which is the basement membrane of the endothelial cells, is synthesized by the endothelial cells

formed from mesenchyme.[1] Listed from outside to inside, the layers that form the mature cornea are the outer epithelium, Bowman's membrane, the secondary stroma, Descemet's membrane, and the corneal endothelium.

Vascular System

The development of the vascular system of the eye is a complex process that involves the appearance of vessels to meet the nutritional needs of the developing eye and subsequent regression of those same vessels.[3] In the early embryo, the internal carotid artery supplies a fine capillary plexus to the dorsal aspect of the optic cup (dorsal ophthalmic artery). Soon afterward, a second branch of the internal carotid artery is given off to supply the medial aspect of the optic cup.[3] This branch is called the ventral ophthalmic artery and is anastomosed with the dorsal ophthalmic artery.[3] The hyaloid artery is a branch of the dorsal ophthalmic artery that passes through the embryonic fissure into the optic cup. Simultaneously, the orbital tissues are supplied by the stapedial artery, a branch of the internal carotid artery.[3] The hyaloid artery extends toward and around the lens vesicle and projects a vascular meshwork across the lens to form the tunica vasculosa lentis.[3] During the sixth week of gestation, the primitive dorsal ophthalmic artery is transformed into the definitive ophthalmic artery, and the ventral ophthalmic artery regresses and transforms into the posterior nasal ciliary artery.[3] The ophthalmic artery's branches become the central retinal artery, the temporal long posterior ciliary artery, and the short posterior ciliary artery.[3] In the third trimester, the hyaloid system begins to regress and the tunica vasculosa lentis becomes thin and atrophic, and eventually disappears.[3–5] Remnants of this system may sometimes be seen in the adult as a persistent pupillary membrane.[6] The hyaloid artery is no longer patent and loses its connection to the disc in the eighth month of intrauterine life (Figs. 8-4 and 8-5). Occasionally, a connective bud may remain attached to the disc as Bergmeister's papilla.[3]

IMAGING TECHNIQUES

Computed tomography (CT) provided a major imaging advance over conventional radiography and multidirectional tomography in examining the eye. However, the development of magnetic resonance (MR) imaging has proven to be an even greater breakthrough in diagnostic medical imaging and biomedical research.[16–20] This section discusses CT and MR imaging of the normal globe and the features of ocular pathology, with particular emphasis on the potential of MR imaging in the practice of ophthalmology.

MR Imaging

The success of MR imaging depends on the cooperation of the patient and, in the case of infants and children, appropriate sedation. The procedure should be carefully explained to the patient and the family or accompanying persons, especially to the person who will stay in the MR scanner room with the patient. For sedation, oral chloral hydrate (75 to 100 mg/kg body weight) usually affords satisfactory sedation in children up to 2 to 4 years of age. When this proves inadequate, intramuscular diphenhydramine (Benadryl, a one-time dose of 1 mg/kg) or midazolam (Versed, 0.05 to 0.08 mg/kg) for children 5 to 8 years of age can be added.[7] Other children may need intravenous medication or general anesthesia, and there may be variations among institutions regarding the doses and medications used. Because of the importance of monitoring sedated patients, sedation procedures should be performed by a trained, dedicated MR imaging nurse. The patient should be monitored during MR imaging using pulse oximetry, allowing evaluation of the arterial oxygen saturation. When general anesthesia is required, anesthesiologists use MR-compatible monitoring and ventilation equipment.

The majority of MR imaging studies described in this section were performed on a 1.5-T Signa unit (General Electric, Milwaukee) with 3 or 5 mm thick sections, with no gap or a 0, 0.6 to 1.5 mm interslice gap. A complete MR evaluation of the eye should consist of high-resolution axial, coronal, and sagittal images of the eye and surrounding structures. The globe can be successfully evaluated with the standard head coil. The field of view, however, should be maintained between 12 and 16 cm and in plane resolution of 256×192, 256×256, or 512×256. Orbital surface coils are used to improve the spatial resolution of MR images.[21] If they are available, they should be used primarily for lesions limited to the globe and for smaller lesions that may not be detected by a head coil. For intraocular lesions that have invaded the optic nerve and retrobulbar space, a head coil is preferred. The use of contrast-enhanced MR imaging of the orbit and brain, using a head coil, is recommended for the evaluation of children with suspected retinoblastoma and, in particular, for patients with possible subarachnoid seeding of retinoblastoma and those with bilateral disease. This technique allows early detection of optic nerve involvement, orbital spread, or asymptomatic pineoblastoma and suprasellar tumors.[21] Although the examination should always be tailored to the problems of the individual patient, in general for ocular lesions the routine MR imaging examination consists of both T1- and T2-weighted images and precontrast and postcontrast T1-weighted images with and without fat suppression. The suggested head coil or surface coil protocol for ocular MR imaging is as follows:

Axial View
- TR 2000–3000 ms, TE 30/80–120 ms
- 256×192, 3 mm slice thickness, 0.5 mm skip
- Field of view (FOV) 16×16 cm, 2 number of excitation (NEX), no phase wrap (NP)
- This may be replaced by a fast spin echo, single echo, T2-weighted, fat suppression acquisition technique

Precontrast Axial View
- TR 500 ms, TE 20 ms
- 256×192, 3 mm slice thickness, 0.5 mm skip
- FOV 14–16, 2 or 3 NEX, NP

Postcontrast Axial and Coronal Views
- TR 500 ms, TE 20 ms
- 256×192, 2 or 3 mm slice thickness, 0.5 mm skip
- FOV 14–16, 3 NEX, NP

Copyright © 2003, Mosby, Inc. All rights reserved.

Postcontrast Fat Suppression Axial View
TR 500 ms, TE 20 ms
256 × 192, 3 mm slice thickness, 0.5 mm skip
FOV 14–16, 3 NEX, NP

An additional postcontrast, fat suppression, T1-weighted sagittal view may be obtained according to the findings in the axial or coronal sections.

Postcontrast Axial View of the Orbit and Head Using a Head Coil
TR 500 ms, TE 20 ms
256 × 192, 5-mm slice thickness, 1.5-mm skip
FOV 22–24 cm, 1 NEX

Because motion artifact is more pronounced on images obtained with a surface coil due to the inherent sensitivity of the coil, a lesion is sometimes seen better on images obtained with a head coil.[21] With the surface coil, a 3 mm section thickness is used to reduce the problem of partial volume averaging. The thin section has the disadvantage of generating less signal (a small volume), and this may result in a decreased amount of T2-weighted information in later echoes, particularly in rapidly decaying T2-weighted signals. For these reasons, at times a uveal melanoma may be better seen on T2-weighted images obtained with a head coil rather than with a surface coil. This is extremely important because the hypointensity of melanotic tissues in T2-weighted images is an important diagnostic feature of these lesions.[19, 21] Despite the difficulties encountered with inhomogeneity in the face and orbit, fat suppression MR techniques are most often utilized. Fat suppression pulse sequences are important for the detection of intraocular (small) lesions and for the evaluation of extraocular extension of eye tumors and inflammation. Fat suppression is also useful in the T2-weighted acquisitions of the optic nerve and optic pathway.

CT Technique

The CT protocol for intraocular lesions includes 1.5 to 3 mm axial sections of the globe. For all foreign bodies and lesions at 6 o'clock and 12 o'clock, additional direct 3 to 5 mm coronal sections are obtained. Additional 1.5, 3, or 5 mm axial sections (depending on the size of the lesion) of the orbit are obtained following administration of iodinated contrast material (meglumine diatrizoate, 1 ml per pound of body weight). In cases of suspected retinoblastoma and uveal melanoma, additional 5 to 10 mm axial sections of the head are obtained to investigate the possibility of an intracranial abnormality. The major application of CT for ocular lesions is the detection of foreign bodies and intraocular calcification. For intraocular tumors and other intraocular pathology, MR imaging is the preferred initial study.

MR Imaging and Evaluation of Intraocular Foreign Bodies

Despite the many advantages of MR imaging, it may not be indicated as a primary modality in the evaluation of the traumatized eyes harboring a possible intraocular foreign body. This cautionary advice is based on the possibility of additional damage to the injured eye by ferromagnetic foreign bodies that are induced to move during the imaging process. A study conducted in vitro and in vivo (rabbit) experiments to examine the effects of MR imaging (1.5 Tesla Units) on intraocular foreign bodies showed that diamagnetic and paramagnetic foreign bodies were imaged without artifacts and without movement during the imaging process, and ferromagnetic foreign bodies produced large amounts of artifact that prevented meaningful images.[22] All ferromagnetic foreign bodies moved during in vitro imaging. During in vivo imaging, three of four ferromagnetic foreign bodies moved, producing substantial retinal injury. It was concluded that MR imaging is contraindicated in the patient with a traumatized eye and a suspected ferromagnetic foreign body. For those patients with a remote history of a traumatic foreign body, or in metal workers or other high-risk individuals, high-resolution 1.5 mm or thinner CT scans of the orbits and 5 to 10 mm thick CT scans of the head are recommended to rule out the possibility of foreign bodies. Patients with stapedectomy (metallic) or other metallic prostheses that have proved to be safe for 1.5T MR unit should be carefully screened for MR study using a 3T or higher field. Not enough data are available to demonstrate that these devices may not move at field strengths higher than 1.5T.

MR Imaging Artifacts

Motion artifacts may result in marked degradation of MR images. It is important to tell patients to close their eyes during the examination. Artifacts may occur as a result of tattooing of eyelids with iron oxide and even from the external application of eye cosmetics (Fig. 8-11). The artifacts arising from tattooing or related to eye cosmetics usually appear as distortion of the skin contours in the location of the iron oxide. There also may be distortion of the shape of the globe and multiple artifacts consisting of hyperintense areas around the contour of the eyelids.

NORMAL OCULAR ANATOMY

Ocular Structures

The eyeball (eye or globe) is made up of the segments of two spheres of different sizes placed one in front of the other. The anterior, smaller segment is transparent (cornea) and forms about one-sixth of the eyeball. The posterior, larger segment is opaque (sclera) and forms about five-sixths of the eyeball.[23] The anterior pole of the eyeball is the center of curvature of the transparent segment, or cornea. The posterior pole is the center of the posterior curvature of the eyeball, and it is located slightly temporal to the optic nerve. The geometric or optic axis is a line connecting the two poles. The equator lies midway between the two poles. Because the fovea centralis is temporal and slightly inferior to the posterior pole, the visual axis and the optic axis do not coincide.[24]

The eye consists of three primary layers (Fig. 8-11): (1) the sclera, or outer layer, which is composed primarily of

VIEW IMAGE

collagen-elastic tissue; (2) the uvea, or middle layer, which is richly vascular and contains pigmented tissue consisting of three components: the choroid, ciliary body, and iris; and (3) the retina, or inner layer, which is the neural, sensory stratum of the eye.

Tenon's Capsule

The fascial sheath of the eyeball, also called the fascia bulbi or Tenon's capsule, is a thin membrane that envelops the eyeball and separates it from the central orbital fat. It thus forms a socket for the eyeball.[23] Tenon's capsule blends with the sclera just behind the corneoscleral junction and fuses with the bulbar conjunctiva. Tenon's capsule is perforated behind by the optic nerve and its sheath, the ciliary nerves and vessels. The capsule fuses with and extends to the sheath of the optic nerve and the sclera around the entrance of the optic nerve.[25] Septa of fibrous tissue are attached to the outer surface of Tenon's capsule, and near the equator it is perforated by the vortex (vorticose) veins (draining veins of the choroid and sclera).[25] The inner surface of Tenon's capsule is smooth and shiny and is separated from the outer surface of the sclera by the episcleral (Tenon's) space.[25] This is a potential space that is traversed by fibers of loose connective (areolar) tissue, which extend between the fascia and the sclera.[26] The episcleral space starts anteriorly, at the bulbar conjunctiva near the sclerocorneal junction, and extends to the optic nerve, where it firmly attaches to the nerve and then is continuous with the subdural and subarachnoid spaces about the nerve.[26] The tendons of all extrinsic ocular muscles pierce the capsule to reach the sclera. At the site of perforation, the fascial sheath is reflected back along the tendons of these muscles to form on each a tubular sleeve.[23] The connection between the muscle fibers and the sheath is especially strong at the point where the two fuse.[25, 26] For this reason, the muscles retain their attachment to the capsule and do not retract extensively after enucleation (tenotomy).[25, 26] The superior oblique muscle sleeve extends as far as the trochlea. The inferior oblique muscle sleeve extends to the origin of the muscle on the floor of the orbit.[23] The tubular sleeves for the four recti muscles have important expansions. Those for the medial and lateral recti are strong and are attached to the lacrimal and zygomatic bones. Because these expansions may limit the actions of these muscles on the eyeball, they are called medial and lateral check ligaments.[23] Thinner and less distinct expansions extend from the superior rectus tendon to that of the levator palpebrae superior, and from the inferior rectus to the inferior tarsal plate. The inferior part of the fascial sheath of the eyeball is thickened and is continuous medially and laterally with the medial and lateral check ligaments.[23] This hammock-like arrangement of the fascial sheath constitutes what is known as the suspensory ligament of Lockwood.[23] This thickened area receives contributions from the fascia of the inferior rectus and inferior oblique muscles as they cross each other below the eyeball. The close relationship between the suspensory ligament of Lockwood and the tendons of the inferior oblique and inferior rectus muscles makes operations on these muscles very difficult and the results unpredictable.[23] The suspensory ligament is strong enough to provide the eyeball with adequate support in case of maxillectomy. Inflammatory and intraocular neoplastic processes are the most common lesions to involve Tenon's space. In posterior scleritis, episcleritis, Tenon's fasciitis, and pseudotumor, an inflammatory effusion produces a characteristic circular or semicircular distention of Tenon's capsule (Fig. 8-12). Retinoblastomas (Fig. 8-13) and melanomas (Fig. 8-14) also may invade Tenon's space.[21]

Sclera

The sclera is the globe's outer white leathery coat. It extends from the limbus at the margin of the cornea to the optic nerve, where it becomes continuous with the dural sheath.[27] The external side of the sclera lies against Tenon's capsule. The internal surface of the sclera blends with the suprachoroidal tissues.[27] Posteriorly the sclera is perforated by the vortex veins, the long posterior ciliary arteries and nerves, and the short posterior ciliary arteries and nerves.

VIEW IMAGE

tendinous insertions of the recti muscles.[23] At the corneoscleral junction the sclera is 0.8 mm thick. The medial rectus muscle inserts 5.5 mm posterior to the limbus; the inferior rectus 6.5 mm; the lateral rectus 6.9 mm; and the superior rectus 7.7 mm.[23] The insertions of the superior oblique and inferior oblique muscles are posterior to the scleral equator. The sclera is perforated posteriorly about 3 mm medial and 1 mm above the posterior pole by the optic nerve. The site of this perforation is referred to as the posterior scleral foramen.[23] Here the sclera is fused with the dural and arachnoid sheaths of the optic nerve. The lamina cribrosa is where the optic nerve fibers pierce the sclera. One of the openings in the lamina is larger than the rest and transmits the central retinal artery and vein. Since the lamina cribrosa is relatively a weak point, it can be made to bulge outward by a rise in intraocular pressure, producing a cupped disc. The sclera is pierced anteriorly at the insertion of the recti muscles by the branches of anterior ciliary arteries. Each rectus muscle has two anterior ciliary arteries, with the exception of the lateral rectus muscle, which only has one.[23]

The sclera is pierced about 4 mm posterior to the equator of the eye by the vortex veins (four or five). The posterior scleral apertures are numerous and are located around the optic nerve. They transmit the long and short ciliary nerves and vessels.[23] Anteriorly, the sclera is continuous with the cornea. Just posterior to the corneoscleral junction, and lying within the sclera, is a circularly running canal called the sinus venous sclerae or the canal of Schlemm. The sclera may be divided, for purpose of description, into three layers: (1) the episclera, (2) the scleral stroma, and (3) the lamina fusca.[23] The episclera is the outermost layer and consists of loose connective tissue. It is connected to Tenon's capsule by fine strands of tissue. Anteriorly, the episclera has a rich blood supply from the anterior ciliary arteries, which form a plexus that extends between the extrinsic muscle insertions and the corneoscleral junction. These vessels lie deep to the

Copyright © 2003, Mosby, Inc. All rights reserved.

conjunctiva and normally are nonconspicuous. However, in the presence of inflammatory disease they become very red and congested. The scleral stroma consists of dense fibrous tissue intermingled with fine elastic fibers. The lamina fusca is the innermost layer of the sclera. It is separated from the external surface of the choroid by a potential space, the suprachoroidal (perichoroidal) space. Connecting the lamina fusca with the choroid are fine collagen fibers that provide a weak attachment between the sclera and the choroid.[23]

Blood Supply and Nerve Supply of the Sclera

The sclera is a relatively avascular structure. However, anterior to the insertions of the recti muscles, the branches of the anterior ciliary arteries form a dense episcleral plexus. This plexus exists beneath the conjunctiva and is normally inconspicuous; however, in the presence of inflammation involving the cornea, iris, and ciliary body, marked vasodilatation may occur. This pronounced vasodilatation is known as a ciliary flush.[23] This rich blood supply to the anterior episclera results in rapid healing of surgical incisions.[23] The posterior sclera receives small branches from the long and short posterior ciliary arteries. The sclera is innervated by the ciliary nerves that arise from branches of the trigeminal nerve.

Cornea

Microscopically, the cornea consists of five layers. From front to back, they are (1) the corneal epithelium, (2) Bowman's layer (membrane), (3) the substantia propria, (4) Descemet's membrane, and (5) the corneal endothelium. Bowman's layer is acellular and consists of interwoven collagen fibers embedded in intercellular substances. It ends abruptly at the limbus. The substantia propria forms 90% of the corneal thickness. It is transparent and consists of many lamellae of collagen fibers that run parallel to the surface.[23] Descemet's membrane is the basement membrane of the endothelium. It is thicker than the endothelium. The corneal epithelium is stratified and consists of five layers of cells. The corneal endothelium consists of a single layer of flattened cells.[23]

Blood Supply and Nerve Supply of the Cornea

The cornea is avascular and devoid of lymphatic drainage. It is nourished by diffusion from the aqueous humor and from the capillaries of the sclera and conjunctiva that end at its edge. The cornea is innervated by the ophthalmic division of the trigeminal nerve, mainly through the long ciliary nerves.[23]

Uvea (Choroid, Ciliary Body, and Iris)

The uveal tract lies between the sclera and the retina (Fig. 8-15). The choroid is the section of the uveal tract that lies between the sclera and the retinal pigment epithelium, the outer layer of the retina (Fig. 8-15). It forms a membrane of predominantly vascular tissue extending from the optic nerve to the ora serrata (Fig. 8-15), beyond which it continues as the ciliary body.[23, 27] Its thickness varies from approximately 0.22 mm at the posterior pole to 0.10 mm near the ora, at the optic nerve, where it forms part of the optic nerve canal, and at the point of internal penetration of the vortex veins. Its inner surface is smooth and firmly attached to the retinal pigment epithelium; its outer surface is roughened. It is firmly attached to the sclera in the region of the optic nerve and where the posterior ciliary arteries and ciliary nerve enter the eye. It is also tethered to the sclera where the vortex veins leave the eyeball.[23] This accounts for the characteristic shape of choroidal detachment, which shows valleys at the site of the vortex veins.[28] The choroid can be divided into four layers, which are, extending from internally to externally, Bruch's membrane, the choriocapillaris, the stroma, and the suprachoroidea.[23, 28]

Bruch's Membrane

Bruch's membrane (2 to 4 μm thick) is a tough, acellular, amorphous, bilamellar structure situated between the retina and the rest of the choroid.[29] Microscopically, Bruch's membrane consists of five layers: the basement membrane of the retinal pigment epithelium, the inner collagenous zone, a meshwork of elastic fibers, the outer collagenous zone, and the basement membrane of the choroicapillaris.[23, 30] The function of Bruch's membrane is not exactly known, although it is believed to play a role in the passage of tissue fluid from the choriocapillaris to the retina.[23] When a choroidal tumor breaks through Bruch's membrane, it results in a characteristic mushroom-shaped growth configuration (Fig. 8-16).

Choriocapillaris

The choriocapillaris is the capillary layer of the choroid, lying immediately external to Bruch's membrane. The capillaries are drained by the vortex veins. The choriocapillaris is a visceral type of vasculature containing wide-bore

FIGURE 8-15 Ocular coats and chambers. FIGURE 8-16 Uveal melanoma. Tissue section shows a mushroom-shaped uveal melanoma (*M*) arising from the choroid (*arrowheads*) and breaking through Bruch's membrane (*curved arrows*). The retina (*open arrows*) is elevated to the top of the tumor and is detached (*arrows*) at the slope of the tumor. (From Mafee MF et al. Malignant uveal melanoma and similar lesions studied by CT. Radiology 1985;156:403–408.)

capillaries with fenestrations in the vessels. These openings are covered by diaphragms, which permit the relatively free exchange of material between the choriocapillaris and the surrounding tissues.[31] By contrast, the retinal capillaries show no fenestrations and present a strong barrier to the interchange of material from capillary to retinal tissue.[27] It should be noted that the density of the capillaries is greatest and the bore is widest at the macula.

Choroidal Stroma

The choroidal stroma lies external to the choriocapillaris and consists of blood vessels, nerves, fibroblasts, a collection of immunologic cells, macrophages, lymphocytes, mast cells, plasma cells, and loose collagenous supporting tissue containing melanocytes. The blood vessels of the stroma are branches of the short posterior ciliary arteries and extend anteriorly. The veins are much larger and converge to join four or five vortex (vorticose) veins that drain into the ophthalmic veins.

Suprachoroidea

The suprachoroidea, also called the perichoroidal/suprachoroidal space, is a potential space, approximately 30 μm thick, that lies between the stroma and the sclera.[27] Running across this space are thin pigmented sheets of connective tissue called the suprachoroid lamina.[23] Running in the suprachoroidal space are the long and short posterior ciliary arteries and nerves. At the optic nerve the choroid becomes continuous with the pia and arachnoid.[23]

Blood Supply of the Choroid

The choroid receives its blood supply mainly from the posterior ciliary arteries. A number of recurrent branches arise from the anterior ciliary arteries. All of these arteries are branches of the ophthalmic artery. The four or five vortex (vorticose) veins drain the choroid into the ophthalmic veins.

Function

The most important functions of the uvea are to provide a vascular supply to the eye and to regulate the ocular temperature.[20] The choroid is also responsible for nourishing the pigment epithelium and the outer one-third of the retina.[27] The fenestrations in its capillaries permit proteins and other larger molecules to diffuse through Bruch's membrane, and the selectivity of passage of these materials anterior to Bruch's membrane depends on the retinal pigment epithelium.[27] It is also thought that changes in the blood flow in the choroidal blood vessels may produce heat exchange from the retina.[23] The pigment cells in the choroid absorb excess light, preventing reflection.[23]

Nerve Supply of the Choroid

The choroid is innervated by the long and short ciliary nerves. The long ciliary nerves are branches of the nasociliary nerve, a branch of the ophthalmic division of the trigeminal nerve. They carry sensory nerve and sympathetic fibers. The short ciliary nerves arise from the ciliary ganglion and carry sympathetic and parasympathetic fibers.[23]

Ciliary Body

The ciliary body is continuous posteriorly with the choroid and anteriorly with the peripheral margin of the iris (Fig. 8-15). Considered as a whole, the ciliary body is a complete ring that runs around the inside of the anterior sclera. It is about 6 mm wide and extends forward to the scleral spur (a projecting ridge of scleral tissue along the internal scleral sulcus) and backward to the ora serrata of the retina.[23] On cross section the ciliary body is triangular, with its small base facing the anterior chamber of the eye and its anterior outer angle facing the scleral spur. Its apex extends posteriorly and laterally to become continuous with the choroid.[23] The anterior surface or base is ridged or plicated and is called the pars plicata. The posterior surface is smooth and flat and is called the pars plana. It is the pars plicata that surrounds the periphery of the iris and gives rise to the ciliary processes. The fibers of the zonule of the lens attach to the surface of the pars plicata (Fig. 8-15). The posterior margin of the pars plana has a scalloped edge that fits into and corresponds with the tooth-like edge of the ora serrata. Surgically, the pars plana is an important anatomic structure. Because of its relative avascularity and its position anterior to the retina, incisions through the sclera and choroid into the vitreous should be made at this point to avoid hemorrhagic complications and retinal detachments.

Copyright © 2003, Mosby, Inc. All rights reserved.

The ciliary body is made up of (1) the ciliary epithelium, (2) the ciliary stroma, and (3) the ciliary muscle. The epithelium consists of two layers of cuboidal cells that cover the inner surface of the ciliary body.[23] Embryologically, they represent the two layers of the optic cup. The inner layer of cubical cuboidal cells is nonpigmented and constitutes the anterior continuation of the nervous layer of the retina. These cells also line the anterior chamber.[23] The deeper outer layer consists of cuboidal cells that are packed with melanin pigment and constitutes the anterior continuation of the pigmented layer of the retina.[23] These cells rest against the stroma of the ciliary body. The structures of the two layers of ciliary epithelium on electron microscopy appear to suggest that both layers are involved in producing aqueous humor.[23] The ciliary stroma consists of loose connective tissue, rich in blood vessels and melanocytes, containing the embedded ciliary muscle. The ciliary muscle consists of smooth muscle fibers. It is innervated by the postganglionic parasympathetic fibers derived from the oculomotor nerve. The nerve fibers reach the muscle via the short ciliary nerves.

Iris

The iris is a thin, contractile, pigmented diaphragm with a central aperture, the pupil (Fig. 8-15). It is suspended in the aqueous humor between the cornea and the lens. The periphery of the iris that is attached to the anterior surface of the ciliary body is called the ciliary margin or root of the iris.[23, 32] The iris divides the space between the lens and the cornea into an anterior and a posterior chamber. The aqueous humor, formed by the ciliary processes in the posterior chamber, circulates through the pupil into the anterior chamber and exits into the sinus venosus (canal of Schlemm) at the iridocorneal angle.[23, 32] The iris consists of a stroma and two epithelial layers located posteriorly and derived from the neural ectoderm. The stroma consists of highly vascular connective tissue containing melanocytes. The stroma also contains nerve fibers, the smooth muscle of the sphincter pupillae, and the myoepithelial cells of the dilator pupillae.[23] The nerve supply of the sphincter pupillae is from the parasympathetic postganglionic fibers in the short ciliary nerves. They are derived from the oculomotor nerve. The dilator pupillae muscle is a thin layer of myoepithelium.[23] The myoepithelial cells are derived from the anterior layer of the iris pigment epithelium that covers the posterior surface of the iris.[23] The arterial blood supply of the iris is from the major arterial circle located in the stroma of the ciliary body. The major arterial circle is formed from the two long posterior ciliary arteries and the seven anterior ciliary arteries.[23]

Retina

The retina is the internal layer of the eyeball. It is a thin, transparent membrane having a purplish-red color in living subjects. The external surface of the retina is in contact with the choroid and the internal surface with the vitreous body. Posteriorly the retina is continuous with the optic nerve. The optic nerve and the inner layer of the eye represent an anteriorly protruding portion of the brain. Grossly the retina has two layers: (1) the inner layer, which is the sensory retina, that is, photoreceptors, and the first- and second-order neurons (ganglion cells) and neuroglial elements of the retina (Müller's cells, or sustentacular gliocytes); and (2) the outer layer, which is the retinal pigment epithelium (RPE), consisting of a single lamina of cells whose nuclei are adjacent to the basal lamina (Bruch's membrane) of the choroid.[20, 32]

The retina is very thin, measuring 0.056 mm near the disc and 0.1 mm anteriorly at the ora serrata.[32, 33] It is much thinner at the optic disc and thinnest at the fovea of the macula. The retina consists of a single-layer outer RPE and an inner neurosensory layer, which are both derived from neuroectoderm. The sensory retina extends forward from the optic nerve to a point just posterior to the ciliary body. Here the nervous tissues of the retina end and its anterior edge forms a crenated wavy ring called the ora serrata (Fig. 8-15). The anterior, nonreceptive part of the retina at the ora serrata becomes continuous with the pigmented and nonpigmented columnar cell layers of the ciliary body and its processes. At the iris, both layers of cells continue on its posterior surface, and they both become pigmented. The macula, the center of the retina, lies 3.5 mm temporal to the margin of the optic nerve (Fig. 8-15). The retina is attached tightly at the margin of the optic disc and at its anterior termination at the ora serrata. It is also firmly attached to the vitreous but loosely to the RPE, and it is nourished by the choroid and the RPE.[27] The macula lutea is the retinal area for the most distinct vision.[23] The optic disc is pierced by the central retinal artery and vein. At the disc there is a complete absence of rods and cones. Thus, it is insensitive to light and is referred to as the blind spot. On ophthalmoscopic examination the optic disc is paler than the surrounding retina. The RPE cells contain numerous round or ovoid melanin granules. The cells have numerous functions, including the absorption of light, participation in the turnover of the outer segments of the photoreceptors, and the formation of rhodopsin and iodopsin by storing and releasing vitamin A, which is a precursor of the photosensitive pigment.[23, 33] The RPE cells are joined to each other by tight junctions. This arrangement forms a barrier (blood retinal barrier) that limits the flow of ions and prevents diffusion of large toxic molecules from the choroid capillaries to the photoreceptors of the retina. In oculocutaneous and ocular albinism, there is a lack of melanin pigment in the pigment cells of the retina and the uvea.[23, 33] The neural retina consists of three main groups of neurons: (1) the photoreceptors (cone and rod cells), (2) the bipolar cells, and (3) the ganglion cells. Its also possesses other important neurons, the horizontal cells and the amacrine cells, that modulate their activity.[23, 33] Supporting cells (Müller cells) are also present. The photoreceptors are similar to other sensory receptors elsewhere in the body. The bipolar cells are similar to the neurons in the posterior root ganglia and form the first-order neurons. The ganglion cells are similar to the relay neurons found in the spinal cord and brainstem and form the second-order neurons.[23] The axons of the ganglion cells form the optic nerve, and its fibers become myelinated after they have passed through the lamina cribrosa. The myelin sheaths of these axons are formed from oligodendrocytes rather than Schwann cells. The nerve cells of the lateral geniculate body form the

Copyright © 2003, Mosby, Inc. All rights reserved.

third-order neurons, and their axons terminate in the visual cortex. Thus, the number of neurons involved in conducting light impulses from the retina to the visual cortex is the same as that found in other sensory pathways.[23] Based on light microscopic findings, the retina is said to be composed of 10 layers. These are, from peripheral (farthest away from the center of the eye) to central, (1) the pigment epithelium, (2) the rods and cones, (3) the external limiting membrane, (4) the outer nuclear layer, (5) the outer plexiform layer, (6) the inner nuclear layer, (7) the inner plexiform layer, (8) the ganglion cells, (9) the nerve fiber layer, and (10) the internal limiting membrane. The outer nuclear layer consists of the nuclei of the rod and cone cells. The outer plexiform layer is made up of the synapses between the terminal processes of the rod and cone cells, the bipolar cells, and the horizontal cells. The inner nuclear layer consists of the nuclei of the bipolar cells, the horizontal cells, the amacrine cells, and the Müller cells. The inner plexiform layer is made up of synaptic connections between the bipolar, amacrine, and ganglion cells. The ganglion cell layer consists of the nuclei of the ganglion cells. The nerve fiber layer consists of the axons of the ganglion cells that are converging toward the optic disc. The external and internal limiting membranes are formed by the cell processes of the supporting Müller cells.[23, 33] There are two types of photoreceptors, the rods (110 to 125 million) and the cones (6.3 to 6.8 million).[23] The cones are responsible for vision in dim light. The rods are absent at the fovea. The cones, by contrast, are most dense at the fovea. There are approximately 1 million ganglion cells in each retina and about 100 photoreceptor cells per ganglion cell. The rod cells contain rhodopsin. The cone cells contain several photochemicals, similar in composition to rhodopsin, and are known as iodopsins.[23] The bipolar cells have a radial orientation. One or more dendrites of the bipolar cells pass outward to synapse with the photoreceptor cell terminals. The single axon is directed inward to synapse with ganglion and amacrine cells. The ganglion cells resemble cells found in nervous ganglia. They are situated in the inner part of the retina. The ganglion cells are the second type of neurons in the visual pathway. Most of them are small (midget ganglion cells), but a small number are large.[23] They are absent at the fovea. The ganglion cells are multipolar cells, and their dendrites synapse with the axons of bipolar and amacrine cells. The axons of ganglion cells converge at the exit of the optic nerve at the optic disc. After piercing the lamina, the nerve fibers become myelinated. In some individuals, the ganglion cell axons are partially myelinated; such areas are non-seeing and will produce a blind spot.[23] In addition to rod and cone cells, bipolar cells, and ganglion cells, there are two types of neurons in the retina called horizontal and amacrine cells. The horizontal cells are located close to the terminal expansion of the rods and cones. The horizontal cells respond to the neurotransmitter liberated by the rods and cones following excitation by light.[23] It is believed that the horizontal cells integrate visual stimuli. The amacrine cells are situated close to the ganglion cells. These cells are stimulated by the bipolar cells, which in turn excite the ganglion cells.[23]

The retinal supporting cells are similar to the neuroglial cells. One of them runs radially and is called the Müller cell. These cells fill in most of the space of the neural retina not occupied by the neurons. Other glial-like cells, called retinal astrocytes, perivascular glial cells, and microglial cells, have also been described.[23]

The macula lutea is an oval, yellowish area at the center of the posterior part of the retina. It measures about 4.5 mm in diameter and lies about 3 mm to the lateral side of the optic disc. Its yellow coloration is caused by a yellow carotenoid pigment, xanthophyll, which is present in the retina layers from the outer nuclear layer inward. The fovea centralis is a depression in the center of the macula lutea. It measures about 1.5 mm in diameter. The depression is made by the peripheral displacement of the nerve cells and fibers of the inner layers of the retina, leaving only the photoreceptors in the center. This greater light accessibility explains why this central depression has the most distinct vision. There are no blood vessels overlying the fovea and no rod cells in the floor of the fovea. It is here that the highest concentration of cones exists. The optic disc measures about 1.5 mm in diameter. A rise in CSF pressure causes the optic disc to bulge into the eyeball. It is believed that the pressure on the optic nerve impedes the axoplasmin flow of its fibers, and this causes the optic disc to swell.

Blood Supply of the Retina

The blood supply of the retina is from two sources. (1) The outer lamina, including the rods and cones and outer nuclear layer, is supplied by the choroidal capillaries; the vessels do not enter these laminae, but tissue fluid exudes between these cells. (2) The inner laminae are supplied by the central retinal artery. The retinal arteries are anastomotic end arteries, and there are no arteriovenous anastomoses. The retina depends on both of these circulations, neither of which alone is sufficient.[23] The central retinal artery is the first branch of the ophthalmic artery,[23, 33] measuring about 0.3 mm in diameter, and runs forward adherent to the dural sheath of the optic nerve. It enters the inferior and medial side of the optic nerve about 12 mm posterior to the eyeball. The artery is surrounded by a sympathetic plexus and accompanied by the central vein. It pierces the lamina cribrosa to enter the eyeball. At this location the posterior ciliary arteries form an anastomotic circle in the sclera around the optic nerve. Small branches from this circle penetrate the choroid to supply the optic disc and the adjacent retina. Small anastomoses occur between the branches of the posterior ciliary arteries and the central retinal artery (cilioretinal artery). The central vein of the retina leaves the eyeball through the lamina cribrosa. The vein crosses the subarachnoid space and drains directly into the cavernous sinus or the superior ophthalmic vein. The retina has no lymphatic vessels.

Vitreous

The vitreous body occupies the space between the lens and retina and represents about two thirds of the volume of the eye or approximately 4 ml.[34, 35] All but 1% to 2% of the vitreous is water, which is bound with a fibrillar collagen meshwork of soluble proteins, some salts, and hyaluronic acid.[20, 23, 34, 35] It possesses a network of fine collagen fibrils that form a scaffolding.[23] The vitreous is the largest and simplest connective tissue present as a single structure in the human body.[32] Any insult to the vitreous body may result in

FIGURE 8-17 Diagram demonstrates various intraocular potential spaces. Principal potential spaces include subretinal, suprachoroidal, and subhyaloid spaces. (From Mafee MF et al. Retinal and choroidal detachments: role of MRI and CT. Radiol Clin North Am 1977; 25:487–507.)

a fibroproliferative reaction (such as proliferative vitreoretinopathy), which can subsequently result in a tractional retinal detachment.[20] The vitreous body has been said to be bounded by membranes, such as the anterior and posterior hyaloid membranes.[23] Anteriorly the vitreous body has a saucer-shaped depression for the lens called the hyaloid fossa.[23] The vitreous body is attached to the sensory retina, especially at the ora serrata and the margin of the optic disc.[23] It is also attached to the ciliary epithelium in the region of the pars plana.[23] The attachment of the vitreous to the lens along the periphery of the hyaloid fossa is firm in young people and weakens with age.

Within the vitreous, the hyaloid (Cloquet's) canal (channel) runs forward from the optic disc to the posterior pole of the lens. During fetal life this channel contains the hyaloid artery, a branch of the central artery of the retina. In developing eyes it nourishes the lens. The hyaloid artery disappears about 6 weeks before birth, and the canal becomes filled with liquid.[23] The vitreous body transmits light, supports the posterior surface of the lens, and assists in holding the sensory retina against the RPE.

INTRAOCULAR POTENTIAL SPACES

There are basically three potential spaces in the eye that can accumulate fluid, resulting in detachment of the various coats of the globe (Fig. 8-17)[20, 32, 36, 37]: (1) the posterior hyaloid space, the potential space between the base of the hyaloid (posterior hyaloid membrane) and the sensory retina (Fig. 8-17). Separation of the posterior hyaloid membrane from the sensory retina is referred to as posterior hyaloid detachment[35] (see Fig. 8-17); (2) the subretinal space, the potential space between the sensory retina and the RPE. Separation of the sensory retina from the retinal pigment epithelium is referred to as retinal detachment (Fig. 8-17); and (3) the suprachoroidal space, the potential space between choroid and the sclera. The RPE and Bruch's membrane are tightly adherent to the choroid and become separated only when both layers are torn. However, the choroid is loosely attached to the sclera and can be separated, resulting in choroidal detachment (Fig. 8-17). The hyaloid fossa (patellar fossa) on the anterior surface of the vitreous for the lens is also a potential space called the retrolenticular space. Exudates and hemorrhage can accumulate in this space in some pathologic conditions.[23] Another potential space is the episcleral or Tenon's space, which was described earlier.

NORMAL IMAGING OF OCULAR ANATOMY

Regarding the anatomy and pathology of the globe, MR imaging is a modality that provides both excellent contrast for ocular imaging and good sensitivity for detecting gross as well as incipient pathology.[20, 21, 23, 37, 38] The globe is unique in that it contains both the most (vitreous) and least (lens) water-laden soft tissues in the body.[37, 38] Since the MR appearance of the vitreous and lens is a function of the interaction between tissue protein and water and because of the wide variation in water content of the eye's various tissues, the eye is an ideal organ for an MR imaging study (Fig. 8-18). The vitreous water content is 98% to 99%, that of the cornea is 80%, and that of the lens is 65% to 69%; these differences produce different water proton relaxation times for each of these tissues.[19, 32, 38]

Copyright © 2003, Mosby, Inc. All rights reserved.

The vitreous represents about two thirds of the volume of the eye, or approximately 4 ml.[29] The vitreous humor is a gel-like transparent extracellular matrix composed of a meshwork of 0.2% collagen fibrils interspersed with 0.2% hyaluronic acid, polymers, water (98% to 99%), and a small amount of soluble proteins.[17, 32, 38] In a number of ocular disease states and as part of the aging process, the vitreous can degenerate to a liquid state devoid of collagen.[18, 32, 39] The vitreous is both viscous and gel-like, and has characteristics associated with both the hyaluronic acid and collagen components, respectively. In a manner similar to that of synovial fluid, the vitreous serves as somewhat of a biologic shock absorber.[39] Because the vitreous is a gel composed of long, fixed collagen fibrils bathed only with dilute dissolved proteins, just a fraction of its water content is in contact with macromolecules.[38] Consequently, the bulk of the water in the vitreous relaxes on MR imaging as pure water, with only a small protein–water interaction.[19, 38] Thus the vitreous has T1 and T2 relaxation times that are longer than those of most tissues but are shorter than those of water (Fig. 8-18).

LENS

The lens is made up of three parts: (1) an elastic capsule, (2) a lens epithelium, which is confined to the anterior surface of the lens, and (3) the lens fibers. The capsule envelops the entire lens. The lens epithelium is cuboidal and lies beneath the capsule. It is found only on the anterior surface of the lens. The lens fibers constitute the main mass of the lens. The fibers are formed by the multiplication and differentiation of the lens epithelial cells at the equator. The lens is held in position by a series of delicate fibers known as the suspensory ligament of the lens, or zonule. The zonule fibers arise from the epithelium of the ciliary process.

The lens is approximately 9 mm in diameter and 4 to 4.5 mm thick. Anterior to the lens are the iris and the aqueous humor; posteriorly, the lens is bordered by the vitreous humor (Fig. 8-15). The zonular fibers (zonules of Zinn) are inserted on the outermost surface of the equatorial lens capsule and extend to the ciliary body (Fig. 8-15). Chemically, the lens is 66% water, making the lens the least hydrated organ of the body.[23] The remainder of the lens is composed of protein forming a liquid crystal. On MR imaging the normal lens is characteristically darker than the surrounding fluid-laden tissue on T2-weighted pulse sequences, predominately because of the dominance of its ultrashort T2 relaxation time (Fig. 8-18).[38] The lens nucleus has both a lower water content and a shorter T2 relaxation time than the cortex.

MR imaging provides precise information regarding other ocular structures as well. The anterior chamber is crescent-shaped, is just anterior to the lens, and is almost isointense to the vitreous humor on both short and long TR images (Fig. 8-18A and 8-18B).[32, 38] The ciliary body may be seen on T2-weighted MR images as a hypointense area running from the edge of the lens to the wall of the globe (Fig. 8-19). Differentiation by MR imaging of individual layers of the sclera, choroid, and retina is impossible in the normal eye.[18, 19, 32]

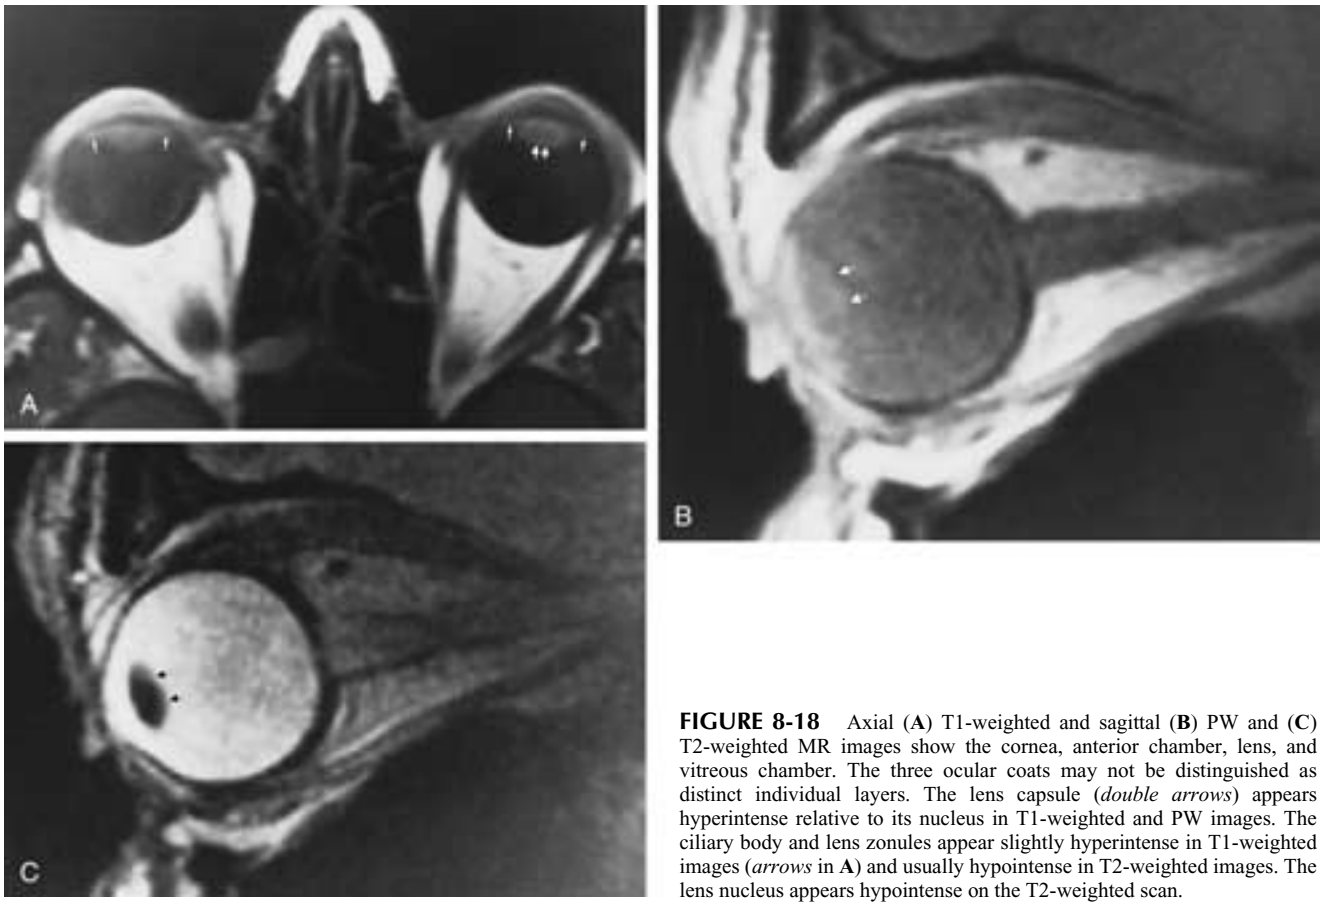

FIGURE 8-18 Axial (**A**) T1-weighted and sagittal (**B**) PW and (**C**) T2-weighted MR images show the cornea, anterior chamber, lens, and vitreous chamber. The three ocular coats may not be distinguished as distinct individual layers. The lens capsule (*double arrows*) appears hyperintense relative to its nucleus in T1-weighted and PW images. The ciliary body and lens zonules appear slightly hyperintense in T1-weighted images (*arrows* in **A**) and usually hypointense in T2-weighted images. The lens nucleus appears hypointense on the T2-weighted scan.

The anterior chamber is a small cavity (3 mm anteroposteriorly) lying behind the cornea and in front of the iris (Fig. 8-15). The chamber contains aqueous humor. Its volume is about 0.2 ml. The aqueous fluid nourishes the corneal epithelium and the lens.[27] The iris, which is the most anterior extension of the uveal tract, lies at the anterior surface of the lens (Fig. 8-15). The ciliary body, which is just posterior to the iris, is responsible for producing aqueous fluid, which drains from the eyeball through the trabecular meshwork at the angle formed by the joining of the root of the iris, the anterior margin of the ciliary body, and the corneoscleral junction.[27] The ciliary body divides the globe into two compartments (segments)—the anterior segment and the posterior segment. The anterior and posterior chambers belong to the anterior segment. The anterior chamber is anterior to the iris and posterior to the cornea (Fig. 8-15). It is filled with aqueous humor. Its volume is about 0.2 ml. It measures about 3 mm anteroposteriorly in its central portion.[23] The posterior chamber is a small stilt-like cavity posterior to the iris and anterior to the lens. Its volume is about 0.6 ml. It is filled with aqueous fluid and communicates with the anterior chamber through the pupil. The posterior chamber is bounded anteriorly by the iris, peripherally by the ciliary processes, and posteriorly by the lens and the zonule (Fig. 8-15).

OCULAR PATHOLOGY

Congenital Anomalies

Anophthalmia

Anophthalmia denotes the complete absence of an eye due to a developmental defect and is extremely rare.[40] More commonly, a small cystic remnant is seen and the term *clinical anophthalmia* is used. Bilateral cases suggest an early teratogenic event related to failure of the optic pit to develop.[40] In true anophthalmia, there is absence of neuroectodermal tissue within the orbit. Those structures not derived from neuroectoderm such as extraocular muscles, eyelids, conjunctiva, lacrimal apparatus, and bony orbit are present; however, the orbit is diminished in size, and orbital soft tissues including the optic nerve and extraocular muscles are rather hypoplastic. In true anophthalmia, in addition to absence of the globes, the optic nerves and the optic chiasm may be absent. The optic tracts may be rudimentary, and the lateral geniculate nuclei may be gliotic.[41] On CT and MR imaging there may be either rudimentary tissue or no globe present. At times, dystropic calcification may be present within the rudimentary tissue. The extraocular muscles, lacrimal glands, and eyelids are present.

Microphthalmia

Microphthalmia refers to a congenital underdevelopment of or acquired diminution in the size of the globe (Fig. 8-20). Congenital microphthalmia (microphthalmos) is a continuation of a spectrum that begins with anophthalmia. Microphthalmos is defined as an eye that has an axial length less than 21 mm in an adult or less than 19 mm in a 1-year-old child.[40] Microphthalmia can occur as an isolated disorder or may be associated with other ocular, craniofacial anomalies (Hallerman-Streiff syndrome) or systemic abnormalities such as MIDS (microphthalmos, dermal aplasia, and sclerocornea).[40] Other causes of microphthalmia include the congenital rubella syndrome, persistent hyperplastic primary vitreous (PHPV), and retinopathy of prematurity (ROP). Bilateral microphthalmia and cataract may be seen in Lowe's syndrome (oculocerebral renal disease).[41] Microphthalmia results from an insult to the embryo after the outgrowth of the optic vesicle. If the insult occurs before complete invagination of the optic vesicle, an orbital cyst may result. This condition is referred to as microphthalmos with *cyst*. It can present as a progressive swelling from birth. The cyst may course along the optic nerve, with free communication with the intraocular contents.

In some cases in which a baby is born with a unilateral small orbit and no visible eye, a small microphthalmic globe is present in the orbital soft tissues. All such children have hypoplastic orbits. CT and MR imaging in congenital microphthalmia demonstrate a small globe as well as a small, poorly developed orbit. In older patients microphthalmia may occur as the result of trauma, surgery, inflammation, radiation, or other processes, which result in disorganization of the eye (phthisis bulbi). In these patients, CT and MR imaging demonstrate a small, shrunken globe, often with extensive intraocular calcification or ossification (Fig. 8-21). The principal conditions with which microphthalmia may be associated are listed in Table 8-1.

Macrophthalmia

Buphthalmos and Megalophthalmos

Macrophthalmia, or enlargement of the globe, is seen in patients with axial myopia, congenital glaucoma (buphthalmos), Sturge-Weber syndrome, and neurofibromatosis. As many as 50% of patients with lid and facial involvement in neurofibromatosis exhibit glaucoma on the affected side. Up to 30% of patients with Sturge-Weber syndrome have glaucoma, and nearly two thirds of these patients develop

Copyright © 2003, Mosby, Inc. All rights reserved.

buphthalmos.[24] The hallmark of all forms of glaucoma in infants and young children is ocular enlargement (Fig. 8-22), which occurs because the immature and growing collagen that constitutes the cornea and sclera in the young eye still responds to increased intraocular pressure by stretching.[40] All parts of the globe may stretch in response to the elevated intraocular pressure until 3 to 4 years of age, and glaucoma-related axial myopia may be seen until the early teenage years.[40] Buphthalmos, the most extreme form of macrophthalmia, consists of elevated intraocular pressure and an enlarged globe, as well as an enlarged cornea. Megalocornea is characterized by bilateral anterior segment enlargement with a corneal horizontal diameter of more than 12 mm at birth and more than 13 mm after 2 years of age. Megalocornea may be present without other ocular abnormalities. Megalophthalmos is an enlarged cornea in an overall enlarged eye that does not have glaucoma. There is an increased ocular axial length, often more than 30 mm. The condition is most likely autosomal recessive, and its findings are similar to those of X-linked megalocornea.[40] The most common cause of macrophthalmia is axial elongation of the eye associated with high myopia.[41] The normal adult eye has an axial length of about 24 mm. Using CT data, the axial length and width of the globe have been

FIGURE 8-20 **A**, Axial CT scan shows a microphthalmic left eye associated with a small calcification. **B**, Axial CT scan in another patient shows bilateral microphthalmia with marked calcifications. **C**, Coronal CT scan of the same patient in **B** showing normal development of the extraocular muscle but hypoplastic optic nerves. **D**, Axial CT scan shows bilateral microphthalmia. published.[42] In addition to ocular elongation, CT and MR imaging may demonstrate thinning of the posterior scleral-uveal rim.

Staphyloma

Staphyloma refers to thinning and stretching (ectasia) of the scleral-uveal coats of the eyeball. Progressive myopia (megamyope) results in posterior staphyloma. The progressively myopic eye expands in all of its posterior dimensions, and the formation of an equatorial staphyloma with scleral dehiscences is not uncommon,[40] especially in the superotemporal quadrant. As the scleral shell expands, the retina and choroid stretch and thin to accommodate the area they cover. Staphyloma has also been reported in glaucoma, scleritis, necrotizing infection after surgery or radiation therapy, and with trauma. Anterior staphyloma also may occur as a result of inflammatory or infectious corneal thinning.[40]

This child presented with eye pain and was found to have cataracts, anterior uveitis of unknown etiology, and glaucoma on the right side. Note the irregularity of the right lens as well as a shallow right anterior chamber (bottom).

Cryptophthalmos

Cryptophthalmos consists of partial or complete failure of development of the eyelids (eyebrow, palpebral fissure, eyelashes, and conjunctiva). It may be unilateral or bilateral. It may be associated with a skin-like cornea, an incompletely developed anterior segment, or a rudimentary cyst-like globe. Cryptophthalmos may be associated with systemic anomalies such as syndactyly and genitourinary anomalies.

Coloboma and Morning Glory Anomaly

A coloboma (Greek, a mutilation) is a notch, gap, hole, or fissure that is congenital or acquired and in which a tissue or portion of a tissue is lacking. Ocular coloboma may involve the iris, lens, ciliary body, retina, choroid, optic nerve, or sclera.[43] Three types of optic nerve colobomas occur: (1) isolated coloboma of the optic nerve, (2) retinochoroidal coloboma, and (3) Fuchs' coloboma.[44–46] In a typical coloboma, the cleft appears in the inferonasal quadrant of the globe and results from the failure of the embryonic fissure to close.[44–46] Fuchs' coloboma (tilted disc syndrome, nasal fundus ectasia syndrome) is a form of coloboma in which there is a congenital, inferiorly tilted optic disc in conjunction with an inferonasal crescent or conus along the border of the disc in the direction of the tilt.[45, 46] Myopia and astigmatism accompany these changes.[45, 46] Ophthalmoscopically, optic nerve coloboma characteristically shows enlargement of the papillary areas, with partial or total excavation of the disc (Fig. 8-23A). The embryonic derivation of the ocular structures was discussed previously in this chapter. A study of this embryology is important to understand the origin of optic nerve colobomas. Isolated

FIGURE 8-23 Typical coloboma of the optic disc. Axial CT scan shows a large posterior global defect (*arrow*) with optic disc excavation on the right side. The defect appears to be surrounded by an enhancing, deformed sclera and seems to have a direct connection with the vitreous body. (From Mafee MF et al. CT of optic nerve colobomas, morning glory anomaly, and colobomatous cyst. Radiol Clin North Am 1987; 25:693–699.)

optic nerve colobomas arise from failure of closure of only the most superior end of the embryonic fissure.[45–47] Failure of closure of other parts of the embryonic fissure causes iridic, lenticular, ciliary body, and retinochoroidal colobomas.[48] The visual acuity in eyes with optic nerve colobomas is variable and may range from normal to abnormal light perception. Both nonrhegmatogenous and rhegmatogenous (tear of the retina) retinal detachments have been well described in association with optic nerve coloboma.[45, 48] Optic nerve colobomas have been observed in association with ocular abnormalities, including congenital optic pit, cyst of the optic nerve sheath, posterior lenticonus, and remnant of the hyaloid artery.[45, 46] These colobomas also have been associated with nonocular abnormalities including cardiac defects, dysplastic ears, facial palsy, and transsphenoidal encephalocele.[49] A coloboma can form in normal-sized eyes as well as microphthalmic eyes. In a small percentage of microphthalmic eyes with coloboma, a defect in the sclera allows an extraocular herniation of the intraocular neural ectoderm to form an orbital cyst with a tunnel-like connection to the globe.[43] The relative sizes of the microphthalmic eye and colobomatous cyst, and the direction of cyst growth, are quite variable (Figs. 8-24 and 8-25). Colobomatous cysts have been associated with a number of systemic syndromes, chromosomal anomalies, and familial cases (Table 8-2).[43]

Morning glory disc is an anomaly that was first characterized by Kindler in 1970.[50] He described a unilateral congenital anomaly of the optic nerve head in 10 patients. Because of the similarity in appearance between the nerve head and a morning glory flower, he referred to the anomaly as the morning glory syndrome. Ophthalmoscopically, the disc is enlarged and excavated and has a central core of white tissue. The disc is surrounded by an elevated annulus of light and also by variable pigmented subretinal tissue.

Diagnostic Imaging

The CT and MR appearance of optic disc coloboma includes a posterior global defect with optic disc excavation (Fig. 8-23). The imaging appearance of the morning glory anomaly is characteristic and corresponds to its clinical appearance as a large funnel-shaped disc (Fig. 8-24). The colobomatous cyst associated with coloboma of the optic nerve head can be readily identified on CT and MR imaging (Figs. 8-25 and 8-26).

FIGURE 8-27 Posterior hyaloid detachment and retinal detachment in a patient with complicated macular degeneration. Sagittal T1-weighted MR image shows two semilunar regions; the posterior region (*white arrows*) is caused by chronic subretinal hemorrhage, and the anterior region (*black arrows*) is caused by posterior hyaloid detachment. Surgery confirmed these findings.

OCULAR DETACHMENTS

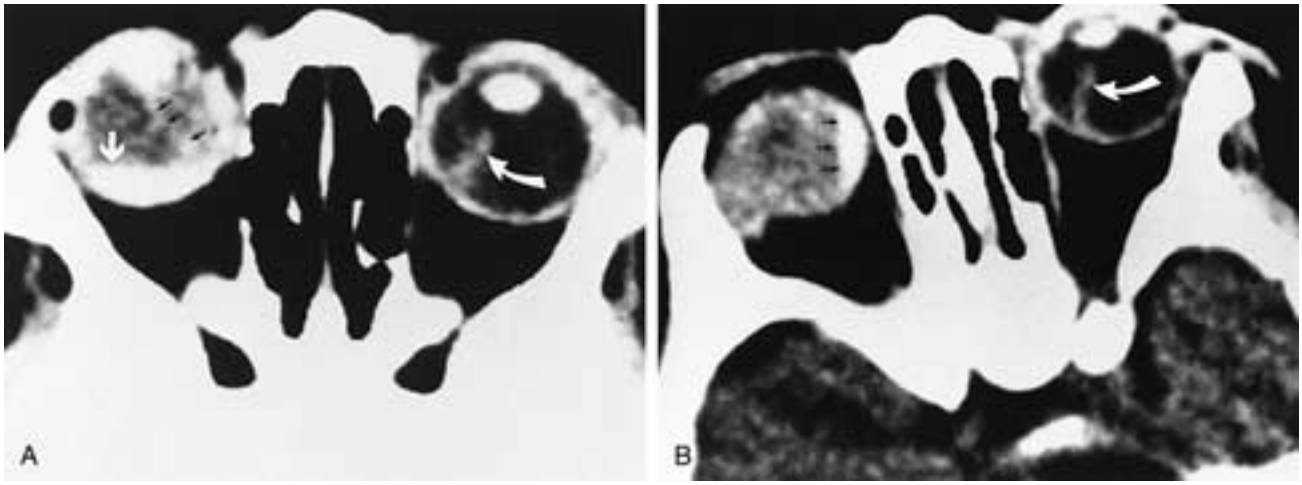
Posterior Hyaloid Detachment

Posterior hyaloid detachment usually occurs in adults over the age of 50 years but may occur in children with persistent hypertrophic primary vitreous (PHPV).[37, 39, 40] In the older population, the vitreous tends to undergo degeneration and liquefaction. This process may lead to posterior vitreous detachment and predispose to retinal detachment.[23] Posterior hyaloid detachment in adults may be associated with macular degeneration (Fig. 8-27).

The posterior hyaloid membrane is very thin and is invisible on MR imaging or CT, but it can be made visible when blood or other fluid fills the posterior hyaloid space, causing thickening of this membrane (Fig. 8-27). Fluid in the retrohyaloid space is seen on CT and MR imaging as a layered abnormality that shifts its location in the lateral decubitus position (Figs. 8-28 and 8-29). The retrohyaloid-layered fluid is shifted in the decubitus position because it is not within the substance of the vitreous (Fig. 8-28B). Hemorrhage within the vitreous mixes with the vitreous humor, which is a gel-like extracellular material and therefore does not show intragel layering. Fluid in the retrohyaloid space and the subretinal space may not be differentiated from each other on CT and MR imaging.[36]

Retinal Detachment

Retinal detachment occurs when the sensory retina is separated from the retinal pigment epithelium. The retinal pigment epithelium has a barrier function that, once damaged, allows fluid to leak into the potential subretinal space.[20, 36] Retinal detachment resulting from a hole (or tear) in the retina is referred to as rhegmatogenous retinal



VIEW IMAGE

FIGURE 8-28 Posterior hyaloid detachment and congenital nonattached retina. Axial CT scans obtained without contrast in the supine position (**A**) and the decubitus position (**B**) show gravitational layering fluid (*white arrow* in **A**), which is related to hemorrhage in the subhyaloid space. Fluid shifts more freely in the subhyaloid space than in the subretinal space (*black arrows* in **B**). Note the congenitally nonattached retina of the left eye (*curved arrows*). Increased density, as well as retrolental soft tissue of the right eye (*black arrows* in **A**), are related to PHPV. (From Mafee MF et al. CT in the evaluation of patients with persistent hyperplastic primary vitreous [PHPV]. Radiology 1982;145:713–717.)

FIGURE 8-29 Posterior hyaloid and retinal detachment. Axial T1-weighted MR image shows the fluid-fluid level (*black arrows*) in the right vitreous chamber. This is thought to be caused by chronic (hyperintense) and acute (hypointense) hemorrhage in the subhyaloid or subretinal space. Note the detached leaves of the retina of the left eye (*white arrows*). The patient was diagnosed as having Warburg's syndrome. (From Mafee MF et al. Persistent hyperplastic primary vitreous [PHPV]: role of CT and MRI. Radiol Clin North Am 1987;25:683–692.)

detachment. The sensory retina is part of the central nervous system, so if there is a tear, the sensory retina cannot heal. By contrast, retinal pigment epithelium has healing potential. In laser treatment for retinal detachment, the energy of the laser beam is absorbed by RPE at the retinal detachment, and the resultant heat heals and closes the tear. Fluid in the subretinal space can be detected by CT and MR imaging (Fig. 8-30). Rhegmatogeneous retinal detachments are rare in the pediatric population. The majority of retinal detachments in children are nonrhegmatogenous and are secondary to other ocular diseases (Fig. 8-31). Retinal detachment usually is the result of retraction caused by a mass, a fibroproliferative disease in the vitreous such as vitreoretinopathy of prematurity or vitreoretinopathy of diabetes mellitus, or accompanying an inflammatory process such as the larval granuloma of toxocara endophthalmitis.[20, 36] Retinal detachment also may occur because of retinal vascular leakage, which is seen in patients with Coats' disease, a primary vascular anomaly of the retina characterized by telangiectasia. The telangiectatic vessels leak serum and lipid, resulting in accumulation of a lipoproteinaceous exudate in the subretinal space (Fig. 8-32). Retinal detachment is sometimes the result of subretinal hemorrhage and occurs following trauma, senile macular degeneration, or persistent hyperplastic primary vitreous. Any choroidal lesions can cause retinal detachment (Figs. 8-33 and 8-34). In an axial CT or MR imaging scan taken below or above the lens, the retinal detachment appears as a homogeneous increased density (Fig. 8-32A). Although the retina is very thin and is beyond the limits of resolution of CT and MR scanners, it may be shown when outlined by the significant contrast difference between the density or intensity of the subretinal effusion on one side and the vitreous cavity on the other side (Fig. 8-35). The appearance of the retinal detachment varies with the amount of exudation (Figs. 8-32 to 8-37) and organization of the subretinal materials. In a section taken at the level of the optic disc, retinal detachment is seen with a characteristic indentation at the optic disc (Figs. 8-36 and 8-37). When total retinal detachment is present and the entire vitreous cavity is ablated, the leaves of the detached retina may not be clearly detected (Fig. 8-38). Retinal detachment is seen on coronal MR imaging as a characteristic folding membrane (Fig. 8-39). The subretinal fluid of an exudative retinal detachment is rich in protein, giving higher CT numbers and stronger MR signal intensities (on T1-weighted MR images) than those seen in the subretinal fluid (transudate) of a rhegmatogenous detachment. A rhematogeneous retinal detachment is produced by a retinal tear and subsequent ingress of vitreous fluid into the subretinal space.[20, 36] In many cases of shallow retinal detachment, the

MR image and in particular the CT scan may not show the detached retina. In these patients, ultrasonography is superior to MR imaging and CT. Retinal detachment is characteristically seen on CT or MR imaging as a V-shaped abnormality, with its apex at the optic disc and its extremities toward the ciliary body (Figs. 8-36 and 8-37). This appearance of retinal detachment may be confused with the appearance of choroidal detachment. However, choroidal detachment, in the region of the optic disc and macula, involves detachment of the choroid that is restricted by the anchoring effect of the vortex veins, short posterior ciliary arteries, and nerves. This restriction usually results in a characteristic appearance of the leaves of the detached choroid, which, unlike the detached

retinal leaves, do not extend to the region of the optic disc (Fig. 8-40).[20, 36]

Inflammatory diseases of the uvea are seldom limited to this vascularized layer of the eye. The sclera and retina are usually involved, producing scleritis or chorioretinitis, respectively. Inflammation of the choroid can damage the retinal pigment epithelial cells. Such damage causes breakdown of the ocular blood barrier, with subsequent outpouring of proteinaceous fluid (exudate) into the subretinal space, producing an exudative retinal detachment.[20] The sensory retina subsequently detaches. Interestingly, neoplastic diseases of the choroid may produce similar changes in the retinal pigment epithelium; however, these changes usually occur in a more advanced stage of the disease (Figs. 8-33 and 8-34).

VIEW IMAGE

Malignant melanomas and choroidal hemangiomas are the most common choroidal neoplasms producing retinal detachment in adults (Figs. 8-33 and 8-34).[19, 36] These tumors produce various degrees of subretinal fluid accumulation, depending on the size and location of the tumor (Figs. 8-33 and 8-34). These tumors produce shifting fluid when the retinal detachment approaches at least one quarter of the circumference of the eye.[20] The subretinal exudate

Choroidal Detachment, Choroidal Effusion, and Ocular Hypotony

Choroidal detachment is caused by the accumulation of fluid (serous choroidal detachment) or blood (hemorrhagic choroidal detachment) in the potential suprachoroidal space.[20, 51–54] Serous choroidal detachment (Fig. 8-40) frequently occurs after intraocular surgery, penetrating ocular trauma, or inflammatory choroidal disorders.[52] Hemorrhagic choroidal detachment often occurs after a contusion, after a penetrating injury, or as a complication of intraocular surgery. Such detachment significantly influences the prognosis of the involved eye.[52] In these cases, ophthalmoscopic visualization of the fundus may be precluded by hyphema (blood in the anterior chamber) or vitreous hemorrhage. Ultrasound, although useful, has

VIEW IMAGE

FIGURE 8-40 Serous choroidal detachment. Axial CT scan shows two prominent linear images (*solid arrows*) in the right eye. Because of the anchoring effect of posterior ciliary arteries and nerves, detached leaves of choroid usually do not appear to converge at the disc, unlike retinal leaves in retinal detachment. The suprachoroidal space (*S*) is isodense with vitreous, indicating serous choroidal detachment. The enlarged right globe results from known congenital glaucoma. Note the postsurgical changes in the left eye and the scleral-encircling silicone band (*curved arrow*). (From Mafee MF et al. Malignant uveal melanoma and simulating lesions: MRI evaluation. Radiology 1986;160:773–780.)

certain shortcomings in examining the traumatized eyes in the presence of an opaque medium. Contact B-scan ultrasound can expel the intraocular contents, is not tolerated by a patient with a painful eye, and increases the risk of inflammation.[54, 55] A-scan ultrasound, though less traumatic, is not often used because it is time-consuming and its interpretation requires experience. If air or gas is present in the vitreous cavity, the ultrasound postoperative evaluation of choroidal detachment is difficult. CT is best suited for the evaluation of a lacerated globe. If there is no suspicion of a ferromagnetic foreign body, MR imaging may be used.

Ocular hypotony is the essential underlying cause of serous choroidal detachment.[52] Ocular hypotony may be the result of inflammatory diseases (uveitis, scleritis), accidental perforation of the eyeball, ocular surgery, or intensive glaucoma therapy.[52–55] The pressure within the suprachoroidal space is determined by the intraocular pressure, the intracapillary blood pressure, and the oncotic pressure exerted by the plasma protein colloids.[51] The capillaries of the choriocapillaris differ from those of other capillary beds in the body because the choriocapillaris is a visceral type of vasculature with fenestrations in the vessels.[27, 31] These openings are covered by diaphragms, which permit the relatively free exchange of material between the choriocapillaris and the surrounding tissues.[27] Ocular hypotony causes increased permeability of the choroidal capillaries. This increased permeability leads to the transudation of fluid from the choroidal vasculature into the uveal tissue and causes diffuse swelling of the entire choroid (choroidal effusion). As the edema of the choroid increases, fluid accumulates in the potential suprachoroidal space, resulting in serous or exudative choroidal detachment.[51, 52, 54, 56] Choroidal effusion, like choroidal hematoma, may be preceded by surgery or other types of trauma to the eye.[57, 58] In fact, choroidal effusion may be a common, albeit transient, occurrence after intraocular surgery.[59] Other causes of choroidal effusion include inflammatory disorders of the eyeball, myxedema, photocoagulation, retinal cryopexy, Vogt-Koyanagi-Harada syndrome, and the uveal effusion syndrome.[59, 60] Clinically the choroidal detachment appears as a smooth gray-brown elevation of the choroid extending from the ciliary body to the posterior segment.[52, 54] Even when the ocular media are clear in pigmented eyes, it is difficult with ophthalmoscopy to differentiate between a serous and a hemorrhagic choroidal detachment.[52, 54] The appearance of serous choroidal detachment on CT has been described.[52] It appears as a semilunar or ring-shaped area of variable attenuation. The degree of attenuation depends on the cause but is generally greater with inflammatory disorders of the eyeball. Inflammatory diseases of the choroid (uveitis) seldom appear as a localized mounding of the choroid; however, they generally produce a diffuse thickening with no localized area of mounding unless there is a choroidal abscess.[20]

Hemorrhagic choroidal detachments appear as either a low or high mound-like area of high density on CT, which can be quite large and irregular (Fig. 8-41). In a fresh hemorrhagic choroidal detachment, the choroid and hemorrhage in the potential suprachoroidal space are isodense. However, in a patient with chronic choroidal hematoma or a serosanguineous choroidal detachment, it may be possible to separate choroid and suprachoroidal fluid accumulation (Fig. 8-42).[52]

MR imaging, with its direct multiplanar imaging ability, is an excellent method for evaluating the eye in patients with choroidal detachment, particularly if ultrasound or CT, in conjunction with the clinical examination, has not provided sufficient information. MR imaging shows a choroidal hematoma as a focal, well-demarcated, lenticular mass in the wall of the eyeball (Fig. 8-43). This characteristic configuration usually does not change as the hematoma ages.[53] However, a decrease in the size of the choroidal hematoma may be observed. Multiple lesions occasionally may be seen (Fig. 8-43). The signal intensity of the choroidal hematoma depends on its age. Within the first 48 hours or so, the hematoma is isointense to slightly hypointense relative to

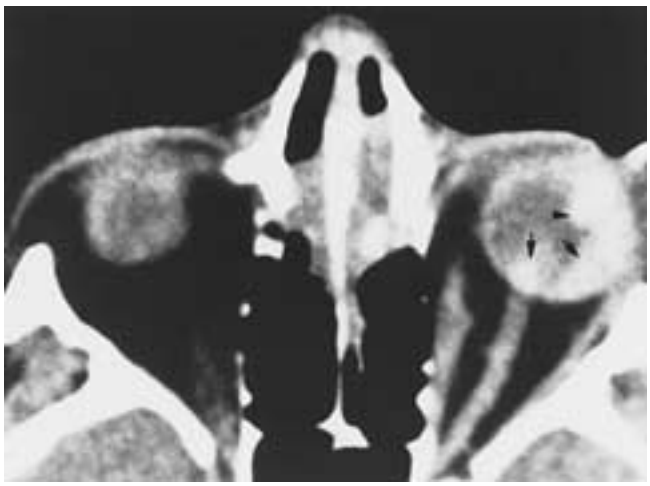

FIGURE 8-41 Acute choroidal hemorrhage (detachment). Axial CT scan shows choroidal hematomas (*arrows*).

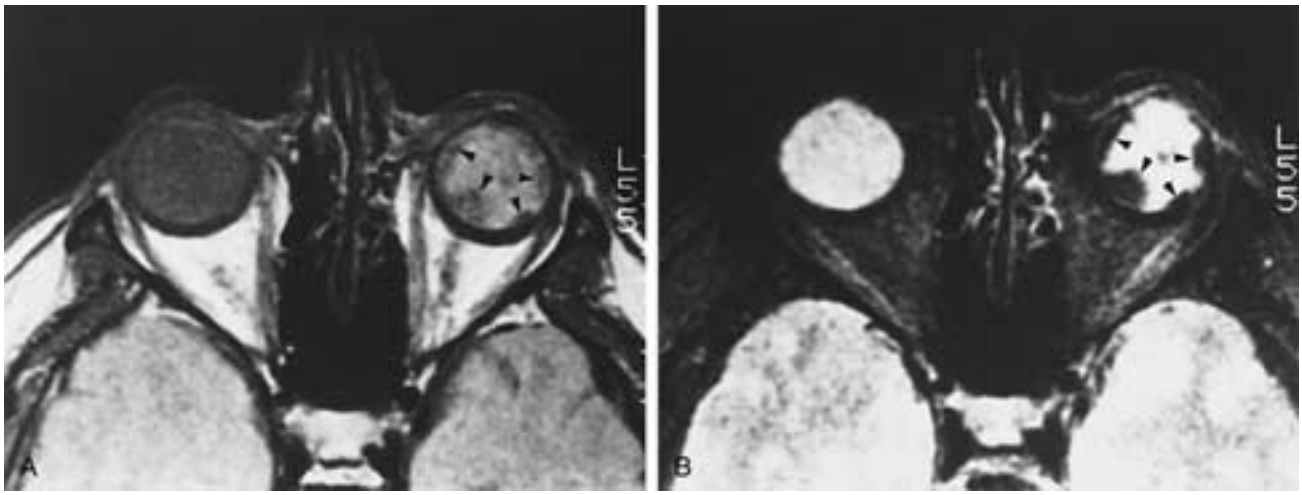
the normal vitreous body on T1-weighted and proton density MR images (Fig. 8-43A) but is markedly hypointense on T2-weighted images (Fig. 8-43B). After 5 days, its signal intensity characteristics are different, being relatively hyperintense on T1-weighted and proton density images (Fig. 8-44A) and only slightly hypointense on T2-weighted images (Fig. 8-44B).[20, 52, 53] At this stage, the choroidal hematoma may be confused with a choroidal melanoma.[53] The hematoma usually continues to increase in signal intensity on T1-weighted, proton density, and T2-weighted images (Fig. 8-44) and usually becomes markedly hyperintense by 2 weeks on all MR sequences (Figs. 8-44 and 8-45).[20, 52, 53]

Serous choroidal detachment (Figs. 8-46 and 8-47) and choroidal effusion (Figs. 8-48 and 8-49) have a different appearance on CT and MR imaging from choroidal hematoma (Figs. 8-41 and 8-43). Serous choroidal detachment is caused by a nonhemorrhagic accumulation of fluid in the suprachoroidal potential space. The choroidal detachment appears as a smooth elevation of the choroid (Figs. 8-46 and 8-47), the fluid in the suprachoroidal space is often hypodense on CT (Fig. 8-46), and its MR appearance is that of an exudate (Fig. 8-47). A choroidal effusion usually is seen as a crescentic or ring-shaped lesion on both CT and MR imaging (Figs. 8-48 and 8-49).[20, 52, 53] It does not resemble the lenticular appearance of a hematoma. Inflammatory choroidal effusions usually appear as increased signal intensity on all MR images (Figs. 8-48 and 8-49). This high signal intensity is thought to be due to the high protein content of the effusion fluid.[53] Posttraumatic effusions, although also demonstrating increased signal on T1-weighted and T2-weighted images, are not as hyperintense as the inflammatory effusions.[53] At times it may be difficult to differentiate retinal detachment and choroidal detachment, since the distinction of choroidal effusion from subretinal effusion is not always clear.[20, 53, 54] Shifting of subretinal fluid occurs rather rapidly, whereas shifting of suprachoroidal fluid occurs slowly.[20] Therefore, rapidly shifting fluid within the wall of the eye, demonstrated on CT or MR imaging, favors the diagnosis of retinal detachment.

Ocular Inflammatory Disorders

The eye may be affected by either known systemic or idiopathic ocular inflammatory processes. A host of infectious diseases may affect the glove. Viral diseases include herpes simplex, rubella, rubeola, mumps, variola, varicella, cytomegalovirus (Fig. 8-50), and infectious mononucleosis. Bacterial diseases include syphilis, brucellosis, tuberculosis, and leprosy. Fungal infections, particularly candidiasis, may also involve the globes in diabetic and immunocompromised patients.[41] Chronic inflammatory processes may cause calcification of the sclera, choroid and



VIEW IMAGE

lens. Extensive disease may result in irregular calcific intraocular masses and a small, deformed globe (phthisis bulbi) (Fig. 8-21).

Other Inflammatory Conditions

Lymphoid Hyperplasia

Lymphoid hyperplasia of the uvea may cause thickening of the posterior wall of the globe, a finding that can simulate melanoma, uveitis, and posterior scleritis (see Fig. 8-12). Lymphoma and leukemic infiltration of the globe may also simulate uveitis.

Papilledema

Increased intracranial pressure may result in papilledema with elevation of the optic discs. On CT and MR scans, elevation and bulging of the optic disc into the posterior aspect of the globe is observed (Fig. 8-51). The diameter of the optic nerve sheath complex may be increased. On postcontrast T1-weighted MR imaging scans, there may be increased enhancement of the optic discs (Fig. 8-51).

FIGURE 8-46 Serous choroidal detachment. **A**, Axial CT scan. **B**, Reformatted sagittal CT image. Scans show detached choroid (*arrows* and *arrowhead*). The suprachoroidal space is isodense to vitreous compatible with serous fluid.

Episcleritis

Episcleritis is a relatively common idiopathic inflammation of the thin layer of tissue lying between the conjunctiva and the sclera. It may be unilateral (66%) or bilateral. In some cases, episcleritis is associated with deeper inflammation (scleritis). Episcleritis is usually self-limited and resolves within 1 to 2 weeks. Imaging evaluation is not indicated in episcleritis.

Scleritis

Scleritis can occur either as an idiopathic condition or in association with systemic diseases.[41] The process may be unilateral or bilateral. Patients with anterior scleritis present with pain, erythema, photophobia, and tenderness.[41, 61] Scleritis may be caused by collagen-vascular disorders, granulomatous diseases, metabolic disorders, infections, and trauma. The sclera is basically an avascular structure deriving its blood supply from the choroidal episcleral plexus.[62] Scleritis may be bacterial, fungal, or viral in origin.[62] It may be caused by metabolic disease (gout) or by a group of autoimmune disorders, including rheumatoid arthritis, polyarthritis nodosa, lupus erythematosus, Wegener's granulomatosis, and relapsing polychondritis.[41, 61] Inflammatory bowel disease, especially Crohn's disease, can be associated with scleritis. Sarcoidosis and Cogan's syndrome also can be associated with scleritis. In most cases of posterior scleritis, however, no underlying cause is found.[61] Scleritis is classified as anterior or posterior scleritis. Scleritis may be acute or chronic. Posterior scleritis results in thickening of the sclera and choroid.[61, 62] There may be associated thickening of Tenon's capsule, as well as secondary serous or exudative retinal detachment (Fig. 8-52).[61, 62] Histopathologically, posterior scleritis is classified into two forms: (1) nodular and (2) diffuse. Nodular posterior scleritis is a focal or zonal necrotizing granulomatous inflammation surrounding a discrete sequestrum of scleral collagen.[61, 62] This type can mimic uveal melanoma (Fig. 8-53). Diffuse posterior scleritis appears as diffuse thickening of the uveoscleral coat, with some degree of contrast enhancement on both CT and MR scans.[61, 62] Fluid between the sclera and Tenon's capsule often causes choroidal detachment, which can be detected by CT and MR imaging or ultrasonography. Perforation of the sclera may be seen in necrotizing scleromalacia, a rare disease usually associated with severe rheumatoid arthritis.[41] At times, in addition to posterior scleritis, other features in support of a diagnosis of pseudotumor may be present on CT and MR scans. These findings suggest that several entities (posterior scleritis, scleritis, sclerotenonitis, periscleritis, and orbital pseudotumor) represent a continuum of the same disease.[62]

Uveitis

Uveitis is an inflammatory process of the intraocular contents, often prominently involving the uveal tract.[41] The etiology of uveitis is often unknown. Many patients appear to have a perturbation of lymphocytic control mechanisms.[41] Intraocular lymphoma can mimic posterior uveitis, pars planitis, or pars plana endophthalmitis; the last condition is an idiopathic form of uveitis. Uveitis may be caused by a specific organism such as *Toxoplasma* or cytomegalovirus. Ocular tuberculosis results from endogenous spread of systemic disease (Fig. 8-54). Toxoplasmosis is a common cause of posterior chorioretinitis. In congenital toxoplasmosis, the fetus is infected in utero and the infection is arrested by the time of diagnosis. Many of these children have cerebral toxoplasmosis and the detection of CNS calcifications by CT helps to establish the etiology.[41] In the adult form of ocular toxoplasmosis, associated CNS involvement is much less common.

This MR appearance may be difficult to differentiate from that of retinal detachment. (From Mafee MF et al. Choroidal hematoma and effusion: evaluation with MRI. Radiology 1988;168:781–786.)

Parasitic Infections

Larval granulomatosis usually affects children between 2 and 8 years of age. The process causes uveitis resulting from ingestion of the eggs of the nematode *Toxocara canis* or *T. cati* (Fig. 8-55).[41] Three clinical patterns occur: (1) a unilateral localized granuloma that may mimic retinoblastoma, (2) endophthalmitis, and (3) pars plana disease.[41]

Intraocular Calcifications

Deposition of calcium in ocular tissues is a complex process, the pathophysiology of which depends on the specific site of calcification. Intraocular calcifications may be metastatic (hypercalcemic states) or dystrophic, and arise in association with diverse degenerative ocular conditions (neoplasia, inflammation, congenital dysplasias, and senescent or traumatic degeneration).[41, 63] Calcifications in neoplasms may be a result of tumor necrosis. Such neoplasms include retinoblastoma and astrocytic hamartomas seen in tuberous sclerosis or neurofibromatosis Type I. Fifty percent of patients with tuberous sclerosis may develop retinal hamartomas, which often calcify. Ocular calcification or ossification may also occur in congenital vascular lesions such as Sturge-Weber syndrome and Von Hippel-Lindau disease.[41] Scleral calcification has been reported in patients with linear sebaceous nevus syndrome.[41] The association of the nevus sebaceous syndrome of Jadassohn with seizures, mental deficiency, and ocular abnormalities has been reported.[41] The ocular anomalies may include coloboma of the iris and choroid, conjunctival lipodermoids, horizontal and rotational nystagmus, and vascularization of the cornea.[41] Chronic posttraumatic degeneration is probably the most common cause of dystrophic intraocular calcification. Choroidal osteoma, episcleral choristoma, and optic disc drusen are other causes of intraocular calcification.[41] Retinopathy of prematurity also may cause delayed unilateral or bilateral ocular calcification.[63] Scleral calcification may be seen in elderly people at or anterior to the sites of insertion of the horizontal extraocular muscles.[63] *Phthisis bulbi* refers to calcification or ossification within a shrunken or atrophic globe. It may be the result of any ocular insult with subsequent degeneration. It is most commonly a result

of trauma or infection.[63] Table 8-3 lists the most frequent causes of intraocular calcifications.[63]

LEUKOKORIA

Leukokoria is a white, pink-white, or yellow-white pupillary reflex (cat's eye). It is a sign that results from any intraocular abnormality that reflects the incident light back through the pupil toward the observer. This reflection of light is the result of a white or light-colored intraocular mass, membrane, retinal detachment, or a retinal storage disease.[40, 64] Leukokoria is dependent on the size, location, and pigmentation of the intraocular pathology. When examining a child with leukokoria, the major diagnostic considerations are retinoblastoma, persistent hyperplastic primary vitreous (PHPV), retinopathy of prematurity (ROP), congenital cataract, Coats' disease, toxocariasis, total retinal detachment, and a variety of other nonspecific diseases.

Leukokoria is the most common presenting sign of retinoblastoma, the highly malignant primary retinal cancer. Howard and Ellsworth studied 500 consecutive patients in whom the diagnostic possibility of retinoblastoma was raised.[65] Of these 500 patients, diagnoses other than retinoblastoma were made in 265 cases (53%). Out of 27 different conditions, the most common was PHPV, followed by ROP, posterior cataract, coloboma of the choroid or optic disc, uveitis, and larval granulomatosis. Identification of the cause of the leukokoria is critical to ensure prompt recognition and appropriate treatment, and diagnostic accuracy is particularly important because retinoblastoma is one of the few human cancers for which definitive treatment is carried out without a confirmed histopathologic diagnosis.[21] Common ocular and orbital disorders in children are listed in Table 8-4.

RETINOBLASTOMA

Retinoblastoma (Rb) is the most common intraocular tumor of childhood. It is a highly malignant primary retinal tumor that arises from neuroectodermal cells (nuclear layer of the retina) that are destined to become retinal photoreceptors.[66, 67] The manner of intraocular and extraocular extension, patterns of metastasis and recurrence, ocular complications, and associated malignancies make the diagnosis of retinoblastoma one of the most challenging problems of pediatric ophthalmology and radiology. To ensure appropriate therapy, retinoblastoma must be differentiated from a host of benign lesions that stimulate it (Table 8-5). This diagnosis must be established rapidly to permit maximum ocular salvage and to minimize tumor-associated mortality.[64, 68] When the disease extends beyond the eye, mortality approaches 100%.[68] With earlier diagnosis, the 5-year survival rate with tumors limited to the globe is greater than 90%.[32, 69] The classification of retinoblastomas has been established in regard to expected results of therapy. Group I includes tumors with a very favorable prognosis. These are either solitary tumors or multiple tumors less than four disc diameters in size at or behind the equator. Useful vision in the treated eye is attained in 90% of these patients and overall in about 75% of eyes that are not enucleated.[69] In group II the prognosis is also favorable, including patients with one or several tumors measuring between 4 and 10 disc diameters. In group III the tumors are anterior to the equator or there is a solitary tumor larger than 10 disc diameters. In these cases the prognosis is guarded. Group IV includes tumors that are multiple and extend up to the ora serrata. Group V includes those tumors that involve half of the retina or tumors that also have vitreous seeds. Groups IV and V have unfavorable prognoses.[21, 32]

Virchow was the first to postulate that retinoblastoma is of glial origin. He used the term *glioma of the retina* to describe the tumor.[32] Bailey and Cushing divided Rb into two types: (1) medulloblastoma and (2) neuroepithelioma. It is now well known that retinoblastoma is derived from primitive embryonal retinal cells (either photoreceptor or neuronal retinal cells).[70] This tumor can be undifferentiated or well-differentiated and can display evidence of photoreceptor differentiation in the form of Flexner-Wintersteiner rosettes and fleurettes.[66, 67, 71, 72] The tumor is composed of small round or ovoid cells with scant cytoplasm and relatively large nuclei. There is marked variability in the histologic features of retinoblastoma. Some tumors display

Rb is unlikely because the lesion appears to have arisen within the uvea rather than the retina. (2) Ocular sarcoidosis panuveitis. **C**, Unenhanced axial T2-weighted (500/13, TR/TE) MR image shows nodular thickening of the posterior aspect of the right globe (*arrow*) and thickening of the anterior segment (*arrowheads*) of the right globe. **D**, Enhanced axial fat-suppressed, T1-weighted (500/13, TR/TE) MR image shows nodular enhancement of the posterior aspect of the right globe (*arrowhead* and *open arrow*) related to granulomatous involvement of the choroids. Note the enhancement of the anterior segment of the right globe and the abnormal enhancement of Tenon's capsule (*curved arrow*). **E**, Enhanced sagittal T1-weighted (400/13, TR/TE) MR image shows granuloma at the optic disc (*white arrowhead*) as well as involvement of the optic nerve (*black arrowhead*). **F**, Enhanced axial fat-suppressed, T1-weighted (500/14, TR/TE) MR image shows enhancement of the markedly thickened uveal tract (*arrowheads*).

significant necrosis and prominent foci of calcification. A few tumors show areas of glial differentiation.[67, 71] The occurrence of a second cancer arising outside the treatment radiation field was pointed out by Jensen and Miller[73] and Abramson, Ellsworth, Kitchin, and Tung.[74] Abramson et al.[74] demonstrated that patients with heritable retinoblastoma are highly susceptible to the development of other nonocular cancers, usually osteogenic sarcomas, and other neoplasms at sites of irradiation. The worldwide incidence of retinoblastoma has been reported to be 1 in 18,000 to 30,000 live births.[75] Although the tumor is congenital in origin, it usually is not recognized at birth.[32] However,

Ocular trauma
Ocular inflammation, including granulomatous conditions
Toxocara larval granulomatosis
Orbital cellulitis—most common cause of proptosis in children
Dermoid and epidermoid cysts—most common orbital masses
Capillary hemangioma and lymphangioma—most common vascular masses
Optic nerve glioma—most common optic nerve tumor in children
Rhabdomyosarcoma—most common primary malignant orbital tumor in children
Leukemia
Pseudotumor
Neurofibroma
Metastatic neuroblastoma—most common metastatic cancer of the orbit in children
Subperiosteal hematoma

ocular involvement and metastasis may be present at birth.[62] In the United States, the average age of the child at diagnosis is 13 months.[76] In other countries, the disease is often not detected until the fourth year of life, when it is usually far advanced.[77] Over 90% of all diagnoses are made in children younger than 5 years of age. The sex distribution is equal, and there is no preference for either the right or the left eye.[78] Retinoblastoma results when an individual retinal cell has inactivation or loss of both alleles of the Rb1 gene on chromosome 13q14.[79–83] Transformation of the retinal cell occurs only if the genetic events occur during the age of vulnerability, usually when the patient is less than 3 years old. Retinoblastoma occurs in two distinct patterns: (1) a nonfamilial sporadic form and (2) a familial, hereditary form that appears at the clinical level to be autosomal dominant.[21] In both forms, the biology of the retinoblastoma tumor is identical. In nonfamilial retinoblastoma, an individual somatic retinal cell undergoes two sequential genetic events resulting in the loss or inactivation of both Rb1 alleles. All of the patients with nonfamilial retinoblastoma have unilateral solitary tumors. In the familial form, the patient's first loss or inactivation of an Rb1 allele occurs during gametogenesis at the germ cell level (either an inherited or a new mutation), so that every cell in the patient has only one working Rb1 allele. Retinoblastoma results if one of the patient's ''primed'' retinal cells has loss or inactivation of the second Rb1 allele (statistically, a 90% chance). With familial retinoblastoma, 85% of the cases are bilateral and 15% are unilateral.[21] Overall, approximately one third of the patients with retinoblastoma have bilateral disease.[19, 78, 84]

A parent with bilateral retinoblastoma has about a 50% chance of passing retinoblastoma on to one child.[78] Some affected children have been found to have an associated deletion of the long arm of chromosome 13 involving band 13q14.[81, 82] The association between retinoblastoma and deletion of the q14 band of chromosome 13j (13q14) has been convincingly documented.[81–83, 85] Esterase D, an electrophoretically polymorphic human enzyme, has also been mapped to chromosomal band 13q14.[86] In several families with hereditary retinoblastoma with no apparent chromosomal deletion, the gene for retinoblastoma has been shown to be closely linked to that for esterase D and assigned to chromosome band 13q14.[86, 87] Compilation of data from recent studies suggests an approximately 7% incidence of 13q chromosomal deletion in patients with retinoblastoma.[88, 89] Only a few of the patients with retinoblastoma have a sufficiently large chromosomal deletion to produce systemic dysmorphic features such as microcephaly, genital malformations, ear abnormalities, mental retardation, and toe and finger abnormalities.[89] Karyotype analysis of these children with congenital dysmorphic features may allow detection of chromosome 13 deletion involving band 13q14, prompting ophthalmic examination and therefore allowing early diagnosis of retinoblastoma.[89] Patients with familial Rb are highly susceptible to the development of other nonocular cancers, usually osteogenic sarcoma, as well as other neoplasms at the site of external beam irradiation (see Fig. 8-31).[32] A second neoplasm may also arise outside the field of radiation.[32] Of 688 patients who survived therapeutic external beam irradiation for retinoblastoma, 89 developed second tumors, 62 in the field of radiation and 27 outside of the field.[32, 74] Of 23 patients who received no radiation, five developed second tumors, either osteosarcoma or soft tissue

sarcoma.[74] The incidence of second tumors is 20% 10 years after initial diagnosis, 50% at 20 years, and 90% at 30 years.[32, 65, 74]

Trilateral Retinoblastoma

The occurrence of ectopic retinoblastoma in the pineal body or in a parasellar region (*trilateral retinoblastoma*) has been reported by Jakobiec et al.[90] and Bader et al.[91, 92] The association of retinoblastoma with pinealoblastoma suggests that these tumors may be related.[93] In addition to having a common neuroectodermal origin, it is well known that in lower vertebrates the pineal gland has photoreceptor functions (similar to those seen in their retinas) and endocrine functions.[93] The development of an ectopic midline neuroblastic tumor in a patient with bilateral retinoblastoma probably represents an additional focus of a multicentric malignancy rather than a second primary tumor or metastatic disease.[91] It is also well known that the histologic appearance of retinoblastomas and pinealoblastomas may not be distinguished from each other.[90] It is postulated that, because of their similar origin, the same mutations may be cancerogenic for both retinoblasts and pinealoblasts. The failure of pineoblastomas to develop in all patients with heritable retinoblastoma may be due to a smaller cell population in the pineal gland or to other unrecognized factors.[94]

Tetralateral Retinoblastoma

Trilateral retinoblastoma is the syndrome of bilateral retinoblastoma with a solitary midline intracranial tumor in the pineal gland, suprasellar region, or parasellar region.[70] El-Nagger et al.[95] reported an 11-month-old infant with bilateral and two distinct partially calcified intracranial tumors: a large mass in the area of the pineal gland and a second tumor in the suprasellar region. On biopsy, the pineal mass was compatible with a neuroblastic tumor (pinealoblastoma). The authors coined the term *tetralateral retinoblastoma* for this case of two distinct midline intracranial neuroblastic tumors associated with bilateral Rb.

Clinical Diagnosis

Retinoblastoma accounts for about 1% of all deaths from childhood cancer in the United States.[96] The diagnosis of retinoblastoma usually can be made by an ophthalmoscopic examination. However, the detection and clinical differentiation of retinoblastoma from a host of benign simulating lesions may be difficult.[35, 82–99] The most common sign associated with retinoblastoma is leukokoria, which is present in 60% of patients (Fig. 8-56).[21, 32, 78] Strabismus (deviation of the eye) is the second most common sign. Pain caused by secondary glaucoma, often with heterochromia (different-colored irides), is the next most common symptom and sign, which leads to ophthalmologic evaluation. The ophthalmologic recognition of retinoblastoma is quite reliable. Small lesions are seen as gray-white intraretinal foci. Because of the difference in color from the surrounding retina and choroid, retinoblastomas can be seen when they are as small as 0.02 mm.[71] Other characteristic ophthalmoscopic findings include tumor calcification and vitreous seeding. As tumors grow in size, they often assume a convex configuration and produce three growth patterns: (1) In endophytic retinoblastoma, the tumor projects anteriorly, breaks through the internal limiting membrane of the retina, and grows into the vitreous. (2) In exophytic retinoblastoma, the tumor arises intraretinally and subsequently grows into the subretinal space, causing elevation of the retina.[64, 86] With continued tumor growth, there is an associated exudation and, rarely, a subretinal hemorrhage, which progressively cause retinal detachment; ophthalmoscopically, the exophytic tumors can simulate a traumatic retinal detachment. (3) In diffuse retinoblastoma, the tumor grows along the retina, appearing as a placoid mass. This diffuse form presents a perplexing diagnostic difficulty because of its atypical ophthalmoscopic feature (which simulates inflammatory or hemorrhagic conditions), its characteristic lack of calcification, and its occurrence usually outside of the typical age group.[64] All three growth forms, but especially the exophytic and diffuse infiltrating forms, may result in a tractional or exudative retinal detachment. Vitreous seeding of the tumor is more common in the endophytic and diffuse forms. Thus retinoblastoma may present as (1) a retinal or subretinal mass, with or without an associated retinal detachment or vitreous opacity; (2) a retinal detachment, with little indication of its etiology; (3) an opaque vitreous, with a limited view of the retinal structures and few clues to the etiology of the vitreous changes; or (4) some combination of the above forms.[64]

Diagnostic Imaging

Although ophthalmoscopic recognition of retinoblastoma is often reliable, imaging modalities should be used on all patients suspected of harboring a retinoblastoma to determine the presence of gross or subtle retrobulbar spread, intracranial metastasis, and the presence of a second tumor. In addition, imaging techniques may allow differentiation of retinoblastoma from lesions such as PHPV, Coats' disease, ROP, toxocariasis, retinal detachment, organized subretinal hemorrhage, organized vitreous, endophthalmitis, retinal dysplasia, retinal astrocytoma (hamartoma), retinal gliosis, myelinated nerve fibers, choroidal hemangioma, coloboma, morning glory anomaly, congenital cataract, choroidal osteoma, drusen of the optic nerve head, and other so-called pseudogliomas and leukokorias. These lesions may have a clinical appearance similar to that of retinoblastoma (Table 8-6). Ultrasonography, CT, and MR are the most useful imaging techniques in the evaluation of these lesions. The tumor and calcification can be diagnosed by ultrasonography; however, the accuracy of ultrasonography for this condition is only 80%.[88] Diagnosis of tumor extension to the medial and lateral aspects of the orbit and extraocular extension are particularly limited with ultrasound.

High-resolution, thin-section (1.5 mm) CT can detect tumor and calcification within it with a high degree of accuracy.[24, 32, 84, 100] More than 90% of retinoblastomas show evidence of calcification on CT.[100] Calcification may be small and single, large and single, multiple and punctate

Posttraumatic or postinflammatory ocular calcification
Bone formation in phthisical eyes
Neurilemoma or neurofibroma of choroid
Intraocular foreign body
Calcification related to macular degeneration
Peripapillary choroidal calcification in chronic retinal detachment

(Fig. 8-56), or a few fine-speckled foci.[84] The DNA released from necrotic cells in retinoblastoma has a propensity to form a DNA–calcium complex. It is the frequent presence of this calcified complex that allows the intraocular tumor to be identified by fundoscopic, ultrasonic, and CT imaging.[32, 84, 100–102] In the extraocular component of retinoblastoma, calcification is rarely present.[84] The presence of intraocular calcification in children under 3 years of age (98% of cases present prior to age 6 months) is highly suggestive of retinoblastoma because none of the simulating lesions, except microphthalmos and colobomatous cyst, contain calcification.[32, 84] Retinoblastoma in a microphthalmic eye is extremely rare. In children over 3 years of age, some of the simulating lesions, including retinal astrocytoma, ROP, toxocariasis, and optic nerve head drusen can produce calcification.[32, 84] The diffuse infiltrating form of retinoblastoma is rare and may have no calcification (Fig. 8-57).[40, 86]

A retinal astrocytoma (astrocytic hamartoma) may initially appear like a retinoblastoma,[32, 76, 84] and the retinal astrocytoma may be present before any of the neurologic or dermatologic manifestations of tuberous sclerosis appear.[84] The CT appearance of these myelinated nerve fibers may also be similar to that of retinoblastoma.[84]

MR Imaging

MR imaging has been used to evaluate retinoblastoma and other simulating lesions.[84, 96, 99, 103–105] In the diagnosis of retinoblastoma, MR imaging is not as specific as CT (Fig. 8-56) because of its lack of sensitivity in detecting calcification. However, the MR imaging appearance of retinoblastoma may be specific enough to differentiate retinoblastoma from simulating lesions (Fig. 8-57).[105] Retinoblastomas appear slightly or moderately hyperintense in relation to normal vitreous on T1-weighted (Fig. 8-56) and proton density images. On T2-weighted images, they appear as areas of markedly (Fig. 8-56) to moderately low signal intensity. Tumors elevated 3 to 4 mm in height may not be definitely identified on MR imaging,[84, 105] and lesions less than 2 to 3 mm in height are not confidently recognized by present MR imaging technology. Calcifications on MR imaging may be seen as varied degrees of hypointensity in all pulse sequences (Fig. 8-56). In contrast to CT scanning, which is highly specific for calcification, MR imaging may be nonspecific. In many cases a calcification may not be recognized on MR imaging (Fig. 8-58). Thus, in the diagnosis of retinoblastoma, CT is more specific because of its superior sensitivity for detecting calcifications. Calcifications as small as 2 mm can be reliably detected by CT.[105] MR imaging, however, has better contrast resolution than CT, and MR imaging provides more information for differentiation of leukokoric eyes.[21, 105] The use of paramagnetic gadolinium contrast material has improved the sensitivity of MR imaging. Retinoblastomas show moderate to marked enhancement on postcontrast MR images (Figs. 8-56 and 8-57).

In a study of 27 patients with leukokoria, MR in all retinoblastomas (17 cases) showed a mass.[105] These masses had relatively short T1 and short T2 relaxation times. All retinoblastomas were seen as mildly to moderately hyperintense lesions on T1-weighted and proton density MR imaging (Figs. 8-56 to 8-58), and this appearance was very similar to that of uveal melanoma. None of the patients with PHPV, ROP, Coats' disease, or toxocariasis demonstrated MR imaging characteristics similar to those of retinoblastomas.[105]

Of the various imaging modalities, MR imaging has become the most useful in evaluating the challenging retinoblastoma patient.[21, 32] Ultrasound is limited by the presence of complex intraocular interfaces when vitreous opacities, retinal masses, subretinal fluid, and retinal detachments are present. As stated, CT is valuable in demonstrating calcification, but both ultrasound and CT are of lesser value in showing local spread of retinoblastoma (Fig. 8-59) or in distinguishing retinoblastoma from stimulating lesions. In the study of eyes with suspected retinoblastoma, our protocol includes plain CT (1.5 to 3 mm thick sections) of the eyes and MR imaging of the eyes and brain, because optic nerve (Fig. 8-59), extracranial (Figs. 8-60 and 8-61) and intracranial involvement (Figs. 8-62 and 8-63) may be better evaluated by MR imaging than by CT scanning. Both techniques can detect the intra- and extraocular lesions; however, MR imaging provides more information about the differentiation of other pathologic intraocular conditions that cause leukokoria, as well as other lesions such as medulloepithelioma and mesoectodermal leiomyoma.[21, 32] Patients with familial retinoblastoma are highly susceptible to the development of other nonocular cancers, usually osteogenic sarcoma as well as other neoplasms at the site of external beam radiation (see Fig. 8-31). Second neoplasms may also arise outside the field of radiation.[21, 32]

Intraocular Mass and Mass-Like Lesions Simulating Retinoblastoma

There are other pediatric intraocular disorders that may clinically simulate retinoblastoma by presenting as a retinal or subretinal mass or mass-like lesion, retinal detachment, or a vitreous opacity.[21, 32] Further taxing the clinician's skills, (1) many of these other intraocular masses or mass-like lesions may secondarily result in retinal detachment or

Copyright © 2003, Mosby, Inc. All rights reserved.

vitreous opacity, (2) the vitreous opacity disorders may secondarily result in a retinal detachment, (3) retinal detachments may undergo organization and contracture so as to resemble an intraocular mass, and (4) secondary cataracts may prevent direct viewing of the primary intraocular condition.

In a study of 500 consecutive patients with leukokoria in whom the diagnostic possibility of retinoblastoma was raised, diagnoses other than retinoblastoma were made in 265 cases.[65] The most common causes of leukokoria include retinoblastoma, PHPV, ROP, Coats' disease, posterior cataract, coloboma of the choroid or optic disc, uveitis, larval granulomatosis, and a variety of other processes (see Table 8-5).[21]

PERSISTENT HYPERPLASTIC PRIMARY VITREOUS

PHPV is a condition that needs to be differentiated from retinoblastoma. Clinically, this condition is characterized by a unilateral leukokoria in a microphthalmic eye of a full-term baby. Rarely, PHPV may be bilateral. It is caused by the failure of the embryonic hyaloid vascular system to regress normally. The basic lesion is caused by a persistence of various portions of the primary vitreous and tunica vasculosa lentis, with hyperplasia and extensive proliferation of the associated embryonic connective tissue. In a study by Howard and Ellsworth,[65] of 500 children with leukokoria, PHPV accounted for 51 of the 265 non-Rb

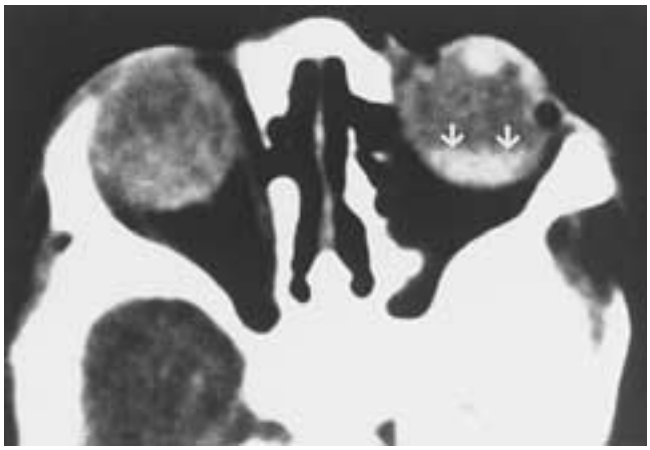
cases. The authors concluded that except for retinoblastoma, PHPV is the most frequent cause of leukokoria in childhood. The nosology of PHPV is extremely complex.[105–107] The ocular malformation can reflect either an isolated congenital defect or a manifestation of more extensive ocular or systemic involvement. The term *persistent hyperplastic primary vitreous* therefore is a marked oversimplification that has no etiologic precision and only the grossest prognostic implications.[108] The embryonic intraocular vascular system may be divided into two components: an anterior system in the region of the iris and a posterior (retrolental) component within the vitreous. The anterior system is composed of the pupillary membrane, which is formed by small vascular buds that grow inwardly to vascularize the iris mesoderm anterior to the lens.[29] The posterior system includes the main hyaloid artery, vasa hyaloidea propria, and tunica vasculosa lentis.[29, 35] The first vessels to undergo regression are the vasa hyaloidea propria, followed by the tunica vasculosa lentis and eventually the main hyaloid artery.[29, 35, 108] During the first month of gestation, the space between the lens and the retina contains the primary vitreous. It consists of two parts: mesodermally derived tissue, including the hyaloid vessel and its branches, and a fibrillar meshwork that is of ectodermal origin.[109] In the second month of embryonic development, collagen fibers and a ground substance or gel component consisting of hyaluronic acid are produced. They form the secondary vitreous and begin to replace the vascular elements of the primary vitreous. By the fourteenth week, the secondary vitreous begins to fill the vitreous cavity.[109] By the fifth to sixth month of development, the cavity of the eye is filled primarily with the secondary vitreous that represents the adult vitreous. The primary vitreous is thus reduced to a small central space, Cloquet's canal, which runs in an S-shaped course between the optic nerve head and the posterior surface of the lens.[35, 36]

Clinical Diagnosis

Diagnosis of PHPV often is made difficult by its extremely broad array of clinical manifestations, etiologic heterogeneity, and frequently opaque ocular media.[106, 108, 110] Complete inspection of the interior of the eye may be precluded not only by cataract but also by vitreous hemorrhage or by opaque retrolental fibrovascular tissue. This condition usually manifests clinically as unilateral leukokoria in a microphthalmic eye. At birth the lens is clear, with a white to pinkish fibrovascular mass behind it; later, the lens usually becomes swollen and cataractous.[111] In the natural course of untreated PHPV, the eye often develops glaucoma and eventually buphthalmos or phthisis,

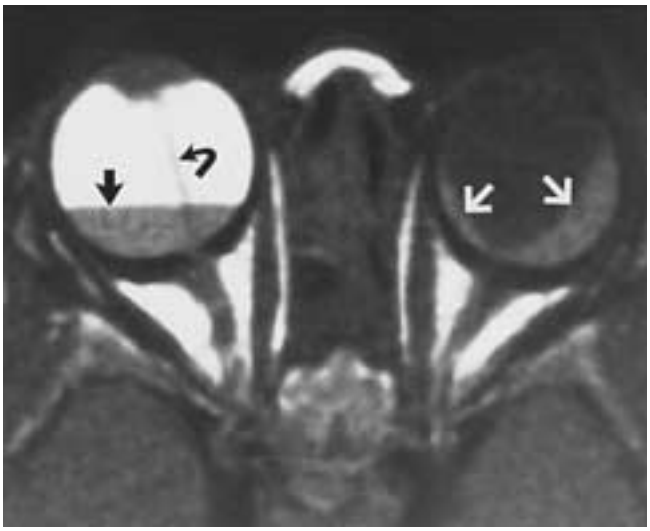
Copyright © 2003, Mosby, Inc. All rights reserved.

sometimes leading to loss of the globe.[111] The clinical presentation of PHPV is variable. Its main features include a unilateral (rarely bilateral) presentation, usually with leukokoria, microphthalmos, lens opacity, retinal detachment, and vitreous hemorrhage. In severe forms, elongated ciliary processes, elongated radial iris vessels, a shallow anterior chamber, and phthisis may occur. The diagnosis of the different types or causes of PHPV can sometimes be inferred from the family and birth histories, as well as from the details of the clinical examination.[108] Direct visualization of remnants of the fetal hyaloid vascular system offers the best evidence. However, direct visualization by ophthalmoscopy or microscopy is sometimes impossible because of the opaque media. In these circumstances, indirect visualization by CT and MR imaging can be diagnostically useful.[35, 108] The CT findings of PHPV were first reported by Mafee and Goldberg and their colleagues.[35, 108] Maximum information was derived from the use of CT following intravenous contrast administration and repeated scanning in the lateral decubitus position.[35] The CT findings include (1) microphthalmos, which is usually detectable, although it may be minimal or absent, and other deformities in the globe configuration, which may have been undetectable by physical examination or ultrasonography;[108] (2) calcification is absent within or around the globe; (3) generalized increased density of the entire vitreous chamber may be visible (Fig. 8-64), although minimally affected patients may show normal attenuation values in the vitreous chambers; (4) enhancement of abnormal intravitreal tissue may be seen after intravenous administration of a contrast medium; (5) tubular, cylindrical, triangular, or other discrete intravitreal densities suggest the persistence of fetal tissue in Cloquet's canal or congenital nonattachment of the retina (Fig. 8-65); (6) decubitus positioning may show a gravitational effect on a fluid level within the vitreous chamber (see Fig. 8-28), reflecting the presence of serosanguineous fluid in either the subhyaloid or subretinal space; and (7) the lens may be small and irregular, and the anterior chamber may be shallow.



VIEW IMAGE

FIGURE 8-64 PHPV. Axial CT scan shows an increase in the density of both vitreous chambers, with gravitational layering of high-density fluid in the left eye (*arrows*). The high-density fluid is most likely caused by blood in the subhyaloid space.



VIEW IMAGE

FIGURE 8-65 PHPV. This 5-month-old girl was diagnosed as having Warburg's syndrome (congenital oculocerebral disorder). Axial T1-weighted MR image shows hyperintense subretinal fluid in the left eye with a detached retina (*arrows*). Note the fluid-fluid level in the right vitreous (*solid arrow*). This is thought to be caused by chronic (hyperintense) and acute (hypointense) hemorrhage in the subhyaloid or subretinal space. Note the tubular image (*curved arrow*), which suggests a congenital nonattached retina or Cloquet's canal.

MR Imaging

The MR appearance of the different types of PHPV may be different. Early experience with MR imaging in patients with PHPV has revealed marked hyperintensity of the vitreous chamber on T1-weighted, proton density, and T2-weighted images.[36] The MR appearance of eyes with ROP may be identical to that of eyes with PHPV. The appearance of retinal detachment in PHPV has two forms: (1) retinal elevation into the vitreous from the optic nerve, resembling acquired forms of retinal detachment (Fig. 8-65), and (2) retinal elevation from a point in the wall of the eye that was eccentric to the optic nerve, suggesting a falciform fold or congenital nonattachment of the retina.[106, 108] Contrast-enhanced CT or MR imaging may demonstrate an enhanced retrolental mass (Fig. 8-66), and there may be increased enhancement in the anterior segment of the involved eye (Fig. 8-66). PHPV is often associated with severe malformations of the optic nerve and retina.[108] The ocular malformation usually reflects a manifestation of more extensive disease including Norrie's disease, Warburg's syndrome, primary vitreoretinal dysplasia, and other congenital defects. Nonetheless, the clinical or imaging detection of PHPV alerts the clinician to the appropriate diagnostic and prognostic possibilities. CT and MR imaging certainly are not indicated if the diagnosis and management of PHPV can be determined easily by conventional techniques. On the other hand, any procedure such as CT or MR imaging that aids the complex diagnostic and therapeutic decision-making that is often required for such affected children should be considered clinically useful and employed in these selected circumstances. In a CT study by Goldberg and Mafee[108] of eight children referred with several

diagnoses, including Rb, congenital cataract, and microphthalmos, after collation of data from clinical examinations under anesthesia and from CT scanning, although PHPV was not the initial diagnosis in any case, it proved to be the most acceptable diagnosis for all patients. MR imaging provides even more information in the diagnosis of PHPV because no patient with PHPV has the hypointensity of the vitreous chamber that is characteristic of retinoblastoma (Figs. 8-56 and 8-57). However, on CT, differentiation of a retinoblastoma from PHPV is not always easy.

RETINAL DYSPLASIA

Retinal dysplasia includes a group of disorders, such as Norrie's disease and Walker-Warburg's syndrome, in which abnormal proliferation and folding of the developing outer retina leads to congenital retinal detachment.[21] PHPV is manifested with more severe malformation in diseases such as Norrie's disease, Warburg's syndrome, and retinal dysplasia.

Norrie's Disease

Norrie's disease, or congenital progressive oculoacousticocerebral degeneration, is a rare X-linked recessive syndrome consisting of retinal malformation, deafness, and mental retardation or deterioration.[112] In 1927, Norrie described seven cases in two families with the same hereditary blindness.[113] In 1961, Warburg described the entity with other congenital eye diseases, coined the eponym *Norrie's disease*,[114] and later added the features of hearing loss and mental retardation. Warburg also described the disorder as *congenital progressive oculoacousticocerebral degeneration*.[115] Warburg established that Norrie's disease has an X-linked recessive pattern of inheritance, affects only males, and has ophthalmologically unaffected female carriers.[116] The affected males can exhibit ocular changes, including partial or complete retinal detachment; vitreoretinal hemorrhage, which can be present in the early neonatal period;[112] a retrolental mass; cataract; glaucoma; optic nerve atrophy; choroidal hypercellularity; and phthisis bulbi, which after varying periods of time lead to bilateral blindness.[112] Other findings include progressive high-tone sensorineural hearing loss,[116, 117] congenital nystagmus,[112] mild to severe mental retardation, and psychotic symptoms.[112, 116, 117]

The pathogenesis of Norrie's disease is unknown. Warburg[116] postulated that the basic lesion is a genetically determined biochemical defect that causes primary arrest in the development of the embryonic neuroectodermal structures of the retina, with consequent changes within the primary and secondary vitreous. Neuroectodermal changes also occur in the cerebral cortex.

Histopathologically, in the early stage the condition is characterized by absence of retinal ganglion cells and absence of normal nerve fiber layer structures in the retina.[118] In the more advanced stages of the disease, most authors have been impressed with the similarity between Norrie's disease and Coats' disease.[119] However, Apple, Fishman, and Goldberg[118] believed that in the earlier stages it is possible to differentiate Norrie's and Coats' diseases. Associated changes in Norrie's disease that may be present include optic nerve atrophy, atrophy of visual pathways, incomplete stratification of the brain cortex, and abnormalities of the brain.[115]

Diagnostic Imaging

The CT findings in Norrie's disease were first reported by Mafee and Goldberg.[35, 108] These included bilaterally dense vitreous chambers (Fig. 8-67A), a retrolental mass, retinal detachment, microphthalmia,[36] optic nerve atrophy, a shallow anterior chamber, and a small, highly dense lens.[36] There was no evidence of intraocular or extraocular calcification, nor was there any evidence of gravitational layering of intravitreal fluid. The MR imaging findings of Norrie's disease include bilateral hyperintense vitreous caused by chronic vitreous or subretinal hemorrhage (Fig. 8-67B,C); persistence of the primary vitreous may be present, the optic nerves may be hypoplastic, and there may be associated developmental anomalies of the brain (Fig. 8-67D).

Warburg's Syndrome

Complex syndromes with congenital malformations of the central nervous system, microphthalmia, and congenital unilateral or bilateral retinal nonattachment have been described in a number of disorders such as Meckel's syndrome, a disorder with malformations of the central nervous system, including encephalocele, cleft palate, polydactyly, cysts of the liver and kidneys, genital malformations, and microphthalmia.[120]

In 1971, Warburg suggested that such patients might suffer from a nosologically distinct syndrome.[121] She described an autosomal recessive disorder consisting of profound mental retardation with death in infancy, hydrocephaly, microphthalmia, and congenital nonattachment of the retina.[121] Subsequent postmortem studies confirmed these clinical observations and noted the coexistence of lissencephaly in these patients.[122, 123]

In 1978 the syndrome was redescribed and the mnemonic HARDTE was coined to point out the following characteristic features: hydrocephaly, agyria, and retinal dysplasia (detachment), with or without encephalocele.[124] The

Copyright © 2003, Mosby, Inc. All rights reserved.

HARDTE, or Warburg's syndrome, is a congenital oculocerebral disorder caused by a genetic defect that simultaneously affects ocular and cerebral embryogenesis and specifically involves the retina and the brain.[125] The syndrome emphasizes the developmental and morphologic similarities between the cerebral cortex and the retina. The syndrome is characterized by congenital bilateral leukokoria.

The ophthalmic findings associated with this syndrome include microphthalmos and retinal dysplasia with congenital retinal nonattachment.[115, 126] Associated anomalies may include vitreous hemorrhage, a large intravitreal vessel, opaque retrolental tissue, persistent hyperplastic primary vitreous, and a hypoplastic optic disc.[125] The lens may have a pear-shaped configuration because of a posterior bulge (posterior lenticonus).[125] Postmortem studies of the brain attest to the poor growth of the cerebral hemisphere, with disorganization and dysgenesis of the cerebral and cerebellar gray and white matter.[122, 123, 125]

Clinical Diagnosis

Microphthalmia and hydrocephaly may be seen in children with congenital toxoplasmosis, rubella syndrome, congenital syphilis, and herpes and cytomegalovirus (CMV) infections. In toxoplasmosis, there may be characteristic chorioretinal scars and a positive serologic test. The presence of significant serum antibody titers against rubella, CMV, herpes virus, and syphilis should serve to distinguish Warburg's syndrome from these simulating disease entities.[32]

Diagnostic Imaging

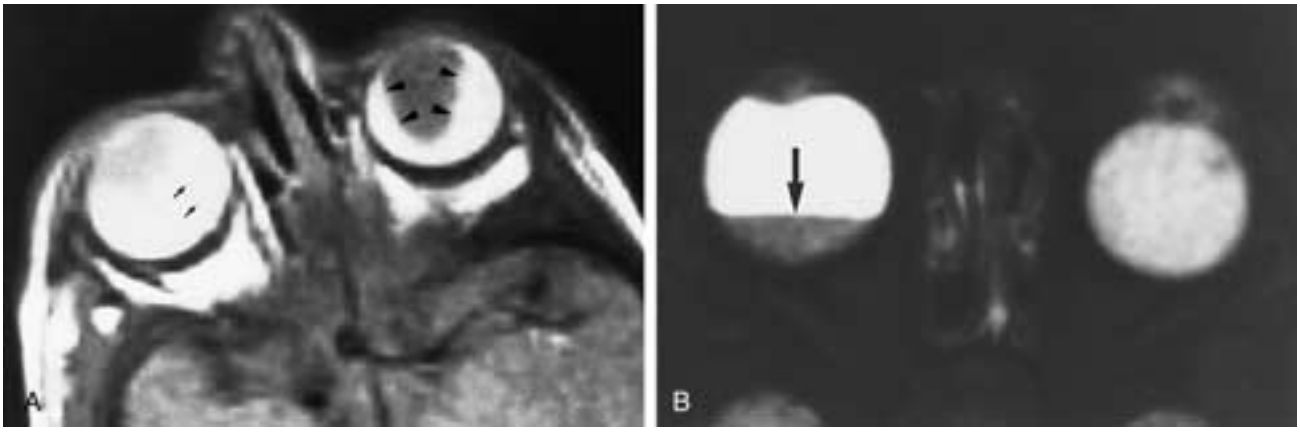
The CT and MR imaging findings in the eyes of patients with Warburg's syndrome include bilateral retinal detachment (Fig. 8-68A), subretinal hemorrhage, vitreous hemorrhage, and gravitational intravitreal fluid (Fig. 8-68B). Persistence of the primary vitreous also may be present.[125] The congenital nonattached retina or the totally detached retina exhibits a characteristic narrow funnel shape or a triangular intravitreal mass adjacent to Cloquet's canal (see Figs. 8-28 and 8-65).

Retinopathy of Prematurity

In contrast to PHPV, ROP (retrolental fibroplasia, retinal fibroplasia) is seen in premature low-birth-weight infants. ROP is usually bilateral and fairly symmetric. The essential feature of ROP appears to be prematurity. The smaller the infant, the greater the risk of developing this disease. ROP usually develops as a response to prolonged exposure to supplemental oxygen therapy. It is possible that excessive oxygen plays only a participating role in the development of ROP. Eller et al.[127] noted that 14 patients had an associated persistent hyaloid vascular system. A massive persistent hyaloid vascular system was found in seven of their patients. The authors concluded that ROP may be related to a combination of developmental and environmental factors that prevent normal retinal vasculogenesis outside the womb.

Ophthalmoscopic Picture

In ROP, proliferation of abnormal peripheral retinal vessels occurs, with subsequent hemorrhage and cicatrization, which may organize and contract, leading to tractional retinal detachment in the advanced stages. The detachment may be partial or total, anterior or posterior, or in an open or closed funnel configuration. The ophthalmoscopic findings of ROP have been divided into active, regressive, and cicatricial phases. The initial active phase is characterized by arteriolar narrowing caused by a spastic response of the vessels to hyperoxia.[128] The vessels then start to dilate and become tortuous. A subsequent sign is the presence of fine, delicate neovascularization in the periphery, changes that are most marked in the temporal periphery because this is the region where the retinal vascularization develops last. Commonly, as long as premature infants are under oxygen therapy, there is no vascular dilatation or tortuosity, which



VIEW IMAGE

FIGURE 8-68 Warburg's syndrome. **A**, Axial T1-weighted MR image shows subretinal effusion with a detached retina (*arrows*) of the left eye. VIEW IMAGE

occurs 24 to 48 hours after the infants are removed rapidly from the oxygen incubator.[129] Gradually, strands containing new vessels pass into the vitreous from the retina. There may be vitreous hemorrhage, which may be massive, and the retina may become partially or completely detached.[129]

Regressive Phase

A characteristic of the disease is that during the early stage, there is a tendency to regress spontaneously, with disappearance of the neovascularization and even of a general detachment of the retina.[129] The detached retina, however, may not always become reattached. About 85% to 90% of cases show spontaneous regression.[129]

Cicatricial Phase

Finally, a dense membrane or a gray-white vascularized mass will be left as permanent evidence of the active phase. The lens always remains clear. The retina is detached, with associated retinal scars. The growth of the eye is often inhibited, with microphthalmos as the final outcome.

Diagnostic Imaging

The early stage of ROP may have no specific CT and MR imaging findings except that the eyes may be microphthalmic. In more advanced cases, the CT and MR differential diagnosis between ROP (Fig. 8-69) and PHPV, retinoblastoma, endophthalitis, or a number of pathologic conditions wherein retinal detachment is a common feature may be difficult.[36, 84, 126, 129] The history of incubator treatment, birth weight, bilaterality, and the ophthalmoscopic, ultrasound, and CT findings are usually sufficient to establish the diagnosis. Calcification is rare in ROP. However, in the more advanced stage, calcification may be present. In the most advanced cases of ROP, both eyes are microphthalmic, with very shallow anterior chambers. Calcification in a microphthalmic eye is less indicative of retinoblastoma, although rarely retinoblastoma has been reported in microphthalmic eyes with or without ROP or PHPV. ROP may on occasion present as unilateral leukokoria. However, in the majority of cases, ROP presents as bilateral but often markedly asymmetric disease.[110] A persistent hyaloid vascular system may be an associated finding in patients with ROP, and the recognition of a massive persistent hyaloid vascular system on clinical examination, MR imaging, CT, or ultrasound is of prognostic importance.[127] In these cases, the surgical dissection of the retrolental membrane in the presence of a persistent hyaloid vascular system is more difficult because these vessels tend to bleed, and the retrolental membrane is tightly adherent to the detached retina.[127]

Coats' Disease

Coats' disease (primary retinal telangiectasis) is a primary vascular anomaly of the retina characterized by idiopathic retinal telangiectatic and aneurysmal retinal vessels, with progressive deposition of intraretinal and

Copyright © 2003, Mosby, Inc. All rights reserved.

subretinal exudates that leads to massive exudative retinal detachment (exudative retinopathy).[27, 130, 131] The condition occurs more frequently in juvenile males than in females. However, it is also seen in adults, in whom it is almost always unilateral.[27, 130, 132, 133] The formation of retinal telangiectasia, and the breakdown in the blood-retinal barrier with leakage of a lipoproteinaceous exudate at the telangiectasis, are the essential underlying causes of the pathologic changes that occur in Coats' disease.[27] The primary cause for the telangiectasis, and for the leakage of serum and lipid and eventual closure of the retinal vessels in the area of the telangiectasis, is unknown.[27] The degree of lipoproteinaceous subretinal exudation in Coats' disease appears to be proportional to the extent of the retinal telangiectasis.[134] The spectrum of pathologic changes in Coats' disease includes intraretinal or subretinal exudation, hemorrhages, lipid and fibrin deposition, phagocytic proliferation (ghost cells), and, ultimately, glial and fibrous tissue organization of the retina.[27] The vascular anomaly of Coats' disease, although present at birth, usually does not cause symptoms until the retina detaches and central vision is lost.[135]

Clinical Presentation and Diagnosis

Coats' disease usually occurs in young boys, with the onset of symptoms in most patients occurring before age 20. Although the incidence peaks between 6 and 8 years,[134] cases have been reported in patients ranging from 4 months old to the seventh decade.[134] The modes of presentation include leukokoria, strabismus, a failed school screening test, or painful glaucoma secondary to angle closure. Although the cause of Coats' disease remains unknown, there are isolated reports associating the disease with fasciocapsulohumeral muscular dystrophy, Turner's syndrome, Senior-Loken syndrome (familial renal-retinal dystrophy), the ichthyosis hystrix variant of epidermal nevus syndrome, inversion on chromosome 3, and a deletion of chromosome 13.[134] The ophthalmoscopic findings in Coats' disease vary with the stage of disease. In the early stages, the telangiectasis can be observed. In the later stages, when the retina is filled with and detached by a mass of cholesterol exudate (total bullous exudative retinal detachment), the telangiectasis can be seen only on fluorescein angiography.[27] In the early stage of the disease, while the retinal disease is not too extensive and the retinal detachment is shallow, photocoagulation, cryotherapy, or both usually obliterate the telangiectatic vessels and reduce or eliminate the exudative retinal detachment.[134] When there is extensive retinal telangiectasis and a total bullous exudative retinal detachment, cryotherapy and photocoagulation may not be sufficient to obliterate the leaking vessels. Such eyes commonly progress to secondary angle closure or iris neovascularization, becoming blind and painful as a result of acute congestive (neovascular) glaucoma.[134, 135]

Diagnostic Imaging

The ophthalmoscopic and biomicroscopic features of eyes with advanced Coats' disease may closely resemble findings in eyes with exophytic retinoblastoma and leukokoria.[136] It is important to distinguish retinoblastoma from Coats' disease. Many eyes with advanced Coats' disease are enucleated because retinoblastoma cannot be excluded.[135] In a study of 62 eyes satisfying the histologic diagnostic criteria of Coats' disease submitted to the Armed Forces Institute of Pathology, Chang, McLean, and Merritt[131] found that 52 (79%) were enucleated, with the diagnosis of retinoblastoma or to rule out retinoblastoma. Coats' disease is almost always unilateral, and it usually appears in boys slightly older (4 to 8 years) than those who have retinoblastoma.[21, 32] Many diagnostic techniques, including ultrasound, CT, and MR imaging, are available that help the ophthalmologist to diagnose clinical conditions, and CT and MR imaging have been shown to be extremely valuable in the diagnosis of Coats' disease.[84, 105, 134]

The CT and MR imaging findings in Coats' disease vary with the stage of the disease. In the early stages, both techniques may yield little information. In the later stages, retinal detachment accounts for all the pathologic findings in CT and MR imaging. Sherman, McLean, and Brallier[137] reported two children with Coats' disease. They concluded that CT could not differentiate between Coats' disease and unilateral noncalcifying retinoblastoma. Haik et al. reported the CT findings in 14 patients with Coats' disease; total retinal detachment (Fig. 8-70A) was routinely seen in advanced disease.[99] Calcification is not a feature of Coats' disease; however, in advanced Coats' disease, in up to one fifth of all cases, there is a fibrous submacular nodule that occasionally is calcified or ossified.[134] These nodules might represent exuberant proliferation and metaplasia of the retinal pigment epithelium (RPE).[134] MR imaging is superior to CT in differentiating Coats' disease from retinoblastomas and other leukokoric eyes.[105, 134] The subretinal exudation of Coats' disease is usually seen as hyperintense on T1-weighted, proton density, and T2-weighted MR images (Fig. 8-70B,C). In retinoblastomas, MR characteristically shows a mass that can be easily differentiated from an associated subretinal exudate. The retinoblastoma is relatively hyperintense on T1-weighted and proton density images (Figs. 8-56 and 8-57) and becomes hypointense on T2-weighted images (Figs. 8-56 and 8-57). The subretinal fluid of an associated retinal detachment is seen as various degrees of hyperintensity in all pulse sequences. Although Coats' disease can produce a subretinal mass resembling retinoblastoma, the mass in Coats' disease is caused by cholesterol, organized hemorrhage, and fibrosis, and therefore its signal is presumed to be inhomogeneous in character. The MR findings in patients with Coats' disease are compatible with retinal detachment without the presence of an intraocular mass (Fig. 8-71). In Coats' disease the detached retina may show enhancement following intravenous injection of Gd-DTPA contrast (Fig. 8-71D). The enhancement is due to idiopathic intraretinal telangiectasia and microaneurysms, the underlying pathology of Coats' disease. The MR findings in some of these patients in the early stages of the disease are normal.

In general, if an ophthalmologist suspects advanced Coats' disease but is uncertain about the correct clinical diagnosis and is unable to rule out retinoblastoma conclusively, a diagnostic imaging study should be requested.[135] When a patient presents with what appears to be a retinoblastoma with total retinal detachment, there are basically three diagnoses to consider: PHPV, Coats' disease, and ROP. In the appropriate clinical setting, the MR imaging and CT findings of Coats' disease should help establish a correct diagnosis.[21, 32, 134]

Ocular Toxocariasis (Sclerosing Endophthalmitis)

Ocular toxocariasis is a chorioretinitis caused by an inflammatory response to the nematode *Toxocara canis*.[21] Infected puppies excrete worm ova that may survive in soil for years. The granuloma of *T. canis* is actually an eosinophilic abscess that contains the second-stage larva of *Toxocara* within it.[21] The infection results from ingestion of the ova (eggs) in contaminated soil. In these patients the death of the larva results in a wide spectrum of intraocular inflammatory reactions,[138–140] the more severe of which has the characteristic pathologic appearance of sclerosing endophthalmitis.[139, 140] Ocular toxocariasis is usually unilateral and is seen in older children. Clinically, it may present as endophthalmitis with vitreous haze from a profound inflammatory response or as posterior or peripheral retinal granuloma.[32] The granuloma appears a white, elevated lesion in the retina and may have associated adherent vitreous bands, vitreous traction, tractional retinal detachment, and dragging of the retina and optic disc.[32] In most but not all instances, the anterior segment is uninvolved, and a funnel-shaped retinal detachment is typically associated with an organized vitreous.[138] The histologic changes of the globe are characterized by an infiltration with lymphocytes, plasma cells, eosinophils, and giant cells. Retinal, subretinal, and vitreous hemorrhages may frequently occur. Remnants of the secondary larval stage of *T. canis* are often difficult to find. In 46 cases originally reported by Wilder,[139] larvae were present in 24. However, in the remaining 22 cases, larvae were not identified. In many cases, the diagnosis of ocular nematode infection is based presumptively on the characteristic histopathologic features of sclerosing endophthalmitis. A diagnostic enzyme-linked immunosorbent assay

(ELISA) for *Toxocara* is now available. In addition, analysis of vitreous fluid by ELISA testing reveals eosinophils. Eosinophilia may not be seen in peripheral blood.[64]

Diagnostic Imaging

Margo et al.[138] reported the CT findings in three cases of histopathologically proven sclerosing endophthalmitis. These findings consisted of a homogeneous intravitreal density that corresponded to a detached retina, an organized vitreous, and an inflammatory subretinal exudate. These investigators concluded that the findings are similar to those seen in Coats' disease and noncalcified retinoblastoma. Three cases of toxocariasis in young adults appeared on CT as a localized or diffuse ill-defined mass with no significant enhancement (Fig. 8-72). Clinical examination in these patients frequently shows vitreous, retinal, or choroidal signs of previous inflammation.[78] This inflammatory process (chronic abscess) is seen on CT as an irregularity of the uveoscleral coat with a diffuse or locally thickened, slightly enhanced uveoscleral coat (Fig. 8-72). This CT appearance usually favors a diagnosis of toxocariasis or another granulomatous disease of the globe and is due to diffuse inflammatory infiltration of the choroid and sclera (Fig. 8-72).[84]

In the appropriate clinical setting, the CT findings of the granuloma of *T. canis* should be relied on to establish a presumptive diagnosis.[84] MR imaging has been reported to have the ability to detect the site of the larval granuloma.[99] The MR images of a patient with a presumptive diagnosis of toxocariasis are shown in Figure 8-55A,B. In general, the proteinaceous subretinal exudate produced by the inflammatory response to the larval infiltration is seen as variably hyperintense on T1-weighted, proton density, and T2-weighted images. These MR imaging characteristics were found in two patients with suspected toxocariasis. Further studies are needed to establish the spectrum of MR imaging characteristics of this relatively uncommon ocular disease. The postcontrast MR imaging appearance of multiple *Toxocara* abscesses in a patient with a positive ELISA test is shown in Figure 8-55C. It should be noted that at times it may be very difficult to differentiate the MR imaging and CT appearances of chronic retinal detachment and organized vitreous from *Toxocara* granuloma, Coats' disease, and even ROP, PHPV, and noncalcified retinoblastoma.[84]

Ocular Astrocytic Hamartoma (Retinal Astrocytoma)

Although retinoblastoma is the major life-threatening cause of leukokoria in children, a host of other simulating conditions (pseudogliomas) can cause diagnostic confusion.[21, 32, 138] In some cases of leukokoria, it is exceedingly difficult to exclude the possibility of retinoblastoma without having to resort to enucleation.[138] Retinal astrocytoma is a benign yellow-white rare retinal tumor that occurs in association with tuberous sclerosis or neurofibromatosis or in isolation.[141] Early retinal astrocytoma (astrocytic hamartoma) may look exactly like early retinoblastoma and may be present before any neurologic or dermatologic manifestations of tuberous sclerosis appear.[32, 78] These tumors may appear in the retina or in the optic nerve. The usual appearance is that of a single nodule or multiple nodules elevated 1 or 2 mm above the surface of the retina. At this stage, CT and MR imaging cannot visualize the lesions. Tumors elevated more than 3 mm can be demonstrated on CT and MR imaging. The CT appearance of astrocytic hamartomas is similar to that of retinoblastoma (Fig. 8-73). If typical features of tuberous sclerosis are not present, the differentiation between astrocytic hamartomas and other ocular lesions may be very difficult. The CT appearance of myelinated nerve fibers in astrocytic hamartomas also may be similar to that of retinoblastoma (Fig. 8-74). In several patients with known tuberous sclerosis and clinical evidence of retinal nodules (dots), because of the small size of the lesions the ocular nodules were not seen on MR imaging.

Combined Hamartoma of the Retinal Pigment Epithelium and Retina

Combined hamartoma of the retinal pigment epithelium and retina is a rare congenital ocular tumor, and patients present with painless loss of vision.[21] This benign proliferation of mature cells involving the retinal pigment epithelium, retina, and vitreous leads to an elevated lesion in the posterior pole or optic disc and occurs with varying pigmentation. The less pigmented lesions simulate retinoblastoma clinically.[21]

Incontinentia Pigmenti

Incontinentia pigmenti is a disorder associated with abnormalities of the skin, eye, and skeletal system.[21] The disease is inherited in an X-linked dominant pattern, although sporadic cases may occur. This condition is lethal in boys. Infants with this condition exhibit pigmentary skin abnormalities including erythematous skin with linear bullae at birth.[21] Ocular involvement is bilateral but often asymmetric. Retinal vascular abnormalities, pigmentary changes, and proliferation of retinal pigment epithelium lead to an intraocular nodular mass (pseudoglioma) that is usually seen in the first year of life. Peripheral fibrovascular proliferation may lead to tractional retinal detachment.[21]

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (non-Langerhans' cell histiocytosis) is a benign cutaneous disorder affecting the skin and eye.[21] The cutaneous lesions are yellow-orange granulomatous nodules composed of histiocytes. This condition usually affects the iris and ciliary body,[142–144] but lesions in the choroid, retina, or optic nerve have also been reported.[143] Juvenile xanthogranuloma has also been noted to present as a solitary orbital granulomatous mass (Fig. 8-75). Infiltration of the iris can cause spontaneous hyphema, glaucoma, and uveitis.

Glioneuroma

Glioneuroma is an exceedingly rare neoplasm that arises from neuroepithelial cells that compromise the anterior margin of the embryonic optic cup.[145] The lesion usually appears at birth or in early childhood but is occasionally diagnosed in adulthood.[145] The tumor appears as a yellow or pink mass in the iris. Histopathologically, the ganglioneuroma is composed of an admixture of glial cells and neurons.[145]

Papillitis

Papillitis, inflammation of the optic nerve head, has multiple causes including ischemia, infections, and autoim-

mune diseases. If the inflammatory process is severe, the optic disc can be massively enlarged and hemorrhagic so as to resemble Rb.[21]

Optic Nerve Head Drusen

Optic nerve head drusen is a benign, usually bilateral cause of pseudopapilledema and is occasionally inherited as an autosomal dominant condition.[146, 147] Disc drusen or hyaline bodies are spherical, acellular, laminated concretions from an unknown source, often partially calcified and possibly related to accumulation of axoplasmic derivatives of degenerating retinal nerve fibers.[146, 147] Drusen are buried within the substance of the nerve head, usually anterior to the lamina cribrosa. They are covered by axonal and glial tissue, together with the vascular supply of the nerve head. Therefore, drusen of the optic nerve head are recognizable because of characteristic distortion in the shape of the nerve head. Drusen of the optic nerve head are usually bilateral. Clinically, the term *drusen* is more frequently applied to the very common multiple small, round, discrete punctate subretinal nodules (drusen of the pigmented retinal epithelium) at the posterior pole. From the standpoint of pathology, drusen of the optic disc should not be confused with drusen of the pigmented retinal epithelium, which are deposits of basement membrane material between the pigment epithelium of the retina and Bruch's membrane. Bruch's membrane is a tough, acellular, amorphous, bilamellar structure situated between the outer layer of the retina, that is, the RPE, and the choroid. Microscopically, Bruch's membrane consists of five layers: (1) basement membrane of the RPE, (2) inner collagenous zone, (3) elastic layer, (4) outer collagenous zone, and (5) basement membrane of the choriocapillaris. RPE drusen are extracellular deposits that lie between the basement membrane of the RPE and the inner collagenous zone of Bruch's membrane. It has been suggested that apoptosis, a process by which cells cast off part of their cytoplasm, may lead to formation of drusen.[63, 146, 147] The RPE drusen are believed to develop by the shedding of basal cytoplasm of RPE through its basement membrane. Over time, RPE and optic disc drusen change their size, shape, and consistency and may become calcified.[63, 146, 147] Drusen contain sialic acid, cerebrosides, calcium, carbohydrate, mucopolysaccharides, and iron. Optic disc drusen may vary in size (from 59 to 750 mm in diameter) and number; often, smaller drusen appear to coalesce to form larger aggregates. Once their calcified component is more than 1 to 1.5 mm, they should be recognized on thin-section (1 to 1.5 mm) CT scans.[146] RPE drusen are not large enough to be visible on CT scans.

Although optic disc drusen are rarely seen in early childhood, most drusen are believed to be present at birth.[146, 147] They become more apparent in later life as they enlarge and approach the disc surface, becoming ophthalmologically visible as hyaline or colloid bodies.[146] Drusen are rarely detected by CT scanning in early childhood. In order to suggest the diagnosis in early childhood, the CT scans should be carefully evaluated, as the optic disc drusen is not calcified enough at this age. Careful evaluation of the optic disc may reveal a small area that is slightly more dense than the rest of the disc. Some children and adults with drusen of the optic disc may undergo a number of diagnostic studies, including cranial CT and MR imaging, to exclude an intracranial process. Optic disc drusen have been reported in 20 to 24 per 1000 patients at autopsy and are bilateral in 73% of cases.[146, 147] When drusen are located well beneath the surface of the disc, they may blur the disc margin and may lead to misdiagnosis of papilledema. Clinically, drusen are usually asymptomatic, but arcuate field defects (arcuate scotomas) or peripheral field constrictions may be present. These field defects are usually not apparent until adulthood, which further emphasizes the slowly progressive nature of drusen. There also appears to be an association between drusen of the optic disc and retinal hemorrhages.[146] Clinical findings in optic disc drusen range from a small, subtle elevation of the disc to a large, globular yellow-white mass containing calcified concretions.[21] On CT drusen appear as discrete, rounded, high-density or calcified bodies that are confined to the optic disc surface and are found at any level within the prelaminar zone of the optic nerve (Fig. 8-76). Optic nerve drusen are difficult to visualize by MR imaging.

VIEW IMAGE

Choroidal Osteoma

Choroidal osteoma is a benign tumor that is typically found unilaterally in young white girls.[21, 63] Histopathologic evaluation reveals mature bone with marrow spaces containing loose fibrovascular tissue.[63] Choroidal osteoma originally was classified as a choristoma (a benign congenital tumor composed of normal tissue elements that do not normally occur at that site), but currently it is regarded by some as an acquired benign choroidal neoplasm of unknown etiology.[145]

Clinical Diagnosis

Patients with choroidal osteoma present with painless progressive loss of vision over several months or years or abrupt recent blurring of central vision. Some lesions are detected initially on routine eye examination.[145] The tumor appears as a yellow-white or orange-red choroidal mass, depending on the amount of depigmentation or hyperplasia of the overlying retinal pigment epithelial layer. This calcified lesion is found in the macula or in the juxtapapil-

Copyright © 2003, Mosby, Inc. All rights reserved.

lary region extending toward the macula.[21] Small vessels can be seen on the surface of the osteoma. Choroidal osteoma involves one eye only in 70% to 80% of cases and both eyes in 20% to 30%.[145] If the lesion involves the macular choroid, visual acuity can be impaired because of degeneration of the overlying RPE and the neurosensory retina.[145] In other cases, a choroidal neovascular membrane arises from the inner surface of the lesion and produces a serous or serosanguineous macular retinal detachment that results in loss of vision.[145]

Imaging Diagnosis

Ultrasound and CT are useful in detecting choroidal osteoma. On a CT scan, choroidal osteomas appear as a plate-like calcified thickening of the posterior ocular wall, typically in the juxtapapillary region; unlike drusen, calcification typically does not involve the center of the optic disc (Fig. 8-77).

Differential Diagnosis

The most important lesions in the differential diagnosis of choroidal osteoma are listed in Table 8-6.

Retinal Gliosis

Retinal and optic nerve astrocytes are analogous to fibroblasts in the body.[21] *Retinal gliosis* refers to reactive proliferation and hypertrophy of astrocytes in the retina, especially occurring in response to injury. Gliotic tissue growth may appear mass-like or may cause tractional retinal detachment.

Myelinated Nerve Fibers

Oligodendrocytes and myelin are not usually present in the human retina.[21] Approximately 1% of eyes have myelinated nerve fibers within the retina, however, usually in a peripapillary distribution. This myelination results in a slightly elevated white retinal plaque and, if extensive, can produce leukokoria. The CT appearance of myelinated nerve fibers may be similar to that of noncalcified retinoblastoma (see Fig. 8-74).

VIEW IMAGE

FIGURE 8-77 Choroidal osteoma. Axial CT scan shows a peripapillary calcified mass (*arrows*) compatible with choroidal osteoma.

X-Linked Retinoschisis

X-linked retinoschisis is a congenital disorder in which there is splitting of the retina within the nerve fiber layer. This causes the inner layers of the retina to be elevated, or the schisis may result in retinal holes, eventually leading to a full-thickness retinal tear and detachment. The CT and MR imaging appearance of X-linked retinoschisis is nonspecific and compatible with retinal detachment.[21]

Retinal Detachment

Retinoblastoma may produce a retinal detachment, which in turn can obscure from view the underlying tumor. Therefore, a retinal detachment resulting from any other etiology can simulate Rb.[21, 32] Rhegmatogenous retinal detachments arise from full-thickness retinal breaks that occur secondarily from retinal atrophy, deterioration, trauma, or vitreous traction. The retinal break allows passage of liquified vitreous into the subretinal space,[21] subsequently causing retinal detachment. Predisposing conditions include trauma, high myopia, Stickler's syndrome, congenital cataract surgery, congenital glaucoma, and myiasis.[21] Nonrhegmatogenous retinal detachments result from traction on the surface of the retina or from exudation under or within the retina, as seen in conditions such as familial exudative vitreoretinopathy, falciform fold, or retinal cyst.[21]

Subretinal Neovascular Membranes

Subretinal neovascular membrane is an acquired abnormality in which growth of new blood vessels from the choriocapillaris occurs beneath the neurosensory retina, usually in response to some retinal injury. These new vessels may hemorrhage or leak, leading to serous retinal detachment. The lesion may organize, resulting in a gliotic, elevated retinal scar and retinal traction.[21]

Vitreous Opacities

Any disease, such as uveitis (see Fig. 8-38), vitreous hemorrhage, endophthalmitis, or organized vitreous, associated with cells in the vitreous can simulate retinoblastoma with vitreous seeding.[21, 32] These vitreous cells or opacities often obscure the view of the retina, causing more difficulty for the clinician in differentiating the etiology of the vitreous cells.

Von Hippel-Lindau Retinal Angiomatosis

Von Hippel-Lindau retinal angiomatosis is an autosomal dominant disorder characterized by retinal capillary heman-

Copyright © 2003, Mosby, Inc. All rights reserved.

giomas.[21] Ophthalmoscopic examination of the fundus reveals a red-orange mass lesion with tortuous feeder and draining vessels.[21] The lesion is usually located in the midperipheral retina and may be associated with exudates and retinal detachment. Aside from ocular conditions, these patients may develop cerebellar hemangioblastoma, optic nerve or optic chiasm hemangioblastoma, renal cell carcinoma, pheochromocytoma, cysts in the kidney or pancreas, and endolymphatic sac tumors.[21]

Choroidal Hemangioma

Choroidal hemangiomas are congenital vascular hamartomas of the choroid that are typically seen in middle-aged individuals. Normal retinal vessels overlie the mass. Choroidal hemangioma in children can simulate retinoblastoma.[21] The CT and MR imaging characteristics of choroidal hemangioma are described elsewhere in this chapter.

Malignant Uveal Melanoma

The uvea (choroid, ciliary body, and iris) is derived from both the mesoderm and the neuroectoderm and may harbor tumors from both of these origins. Because it is the most highly vascular portion of the eyeball, the uvea provides a suitable substrate for tumor cells. Most primary and metastatic ocular neoplasms involve the choroid, and the most common tumor is malignant melanoma.[148] Malignant melanomas of the uvea are unusual in blacks, with the white/black patient ratio being about 15:1.[149] Those melanomas involving the ciliary body and choroid are thought to originate from preexisting nevi.[148] The neoplasm has a capacity to metastasize hematogenously. Its favored metastatic site is the liver. The incidence of malignant melanoma of the choroid has been estimated to be 5.2 to 7.5 cases per million per year.[150] The incidence of uveal melanoma increases with age. Less than 2% of tumors are seen in patients below 20 years of age.[62] Congenital melanosis, ocular melanocytosis, oculodermal melanocytosis, and uveal nevi are predisposing lesions that precede the development of uveal melanoma.[62]

Callender's classification of melanotic lesions, which is based on cellular features, offers the best indication of the prognosis.[151, 152] The spindle-A tumors, which are composed of spindle cells with elongated nuclei, characteristically lacking nucleoli, have the best prognosis. The next best prognoses involve the spindle-B tumors, whose cells have the same shape as spindle-A lesions but are slightly larger and have a nucleus containing a prominent nucleolus. The next worst prognosis concerns the epithelioid-cell tumors, which are composed of larger, more pleomorphic cells than the spindle-cell tumors. Finally, there are mixed-cell tumors composed of both spindle and epithelioid cells.[148, 152] Some of the tumors may be amelanotic, especially the spindle-cell tumors.

Clinical Diagnosis

An iris melanoma is seen as a visible spot on the iris or as a discoloration of the iris in one eye. The typical ciliary body melanoma appears as a highly elevated, nodular, dark brown lesion in the peripheral fundus.[153] The typical choroidal melanoma appears as a dark brown solid tumor and has a biconvex, lenticular cross-sectional shape.[153] The tumor initially grows flat within the choroid, later elevates Bruch's membrane, and finally ruptures through it so that the melanoma assumes a characteristic mushroom shape, growing toward the vitreous cavity. The retina over the surface of the tumor becomes elevated and detached (solid retinal detachment). This detachment gradually extends as a serous detachment over the slopes of the tumor.

Ophthalmoscopically, the lesion is seen as a circumscribed mass of varied pigmentation along with a solid retinal detachment, and the retinal vessels over the surface of the mass are elevated. The retina usually is attached to the mass and does not float easily, as seen in rhegmatogenous retinal detachments. In some cases, the subretinal fluid extends only around the base of the lesion; in others, it accumulates to the extent that the retina is extensively or even totally detached.[153] In some cases, the subretinal fluid is bloody, almost exclusively in eyes that have tumor eruption through Bruch's membrane.[153]

If the tumor is not treated, it may cause secondary glaucoma and eventually break through the eye into the retrobulbar region. Metastases occur primarily to the liver. Management of clinically suspected choroidal melanomas has been the subject of some controversy in recent years. Enucleation has been a standard treatment for more than a century.[154] However, enucleation has not been proven to prevent metastasis. Furthermore, Zimmerman, McLean, and Foster have hypothesized a potentially harmful effect from intraoperative dissemination of tumor cells.[155] The controversy over the efficacy of enucleation remains unresolved.[156]

In general, relatively small choroidal melanomas measuring less than 10 mm in diameter and 3 mm in thickness have a relatively favorable prognosis, with a 10% to 15% incidence of death in 5 years.[157] Biologic aggressiveness has been judged by a clinically visible increase in the size of the tumor. Clinically stable choroidal melanomas are managed with longitudinal observations by clinical examination, echography, CT, and MR imaging, and no treatment. Nevertheless, visibly stationary melanomas have been capable of extensive extraocular extension and possibly even distant metastasis.[158, 159] Furthermore, it has been suggested that tumor cell dissemination may occur early in the course of the disease, with distant metastasis appearing many years later.[160] Thus the clinical management of even small and relatively stable choroidal melanomas warrants careful consideration and the use of all reasonable clinical aids.[156] If there is evidence of tumor growth, enucleation, or local excision, other modes of therapy such as photocoagulation and radiation therapy are indicated.[157, 161] Some advocate early enucleation of all melanomas to prevent metastasis.[160] Metastatic sites of primary uveal melanoma include liver, lung, bone, kidney, and brain in order of decreasing frequency, and a thorough search for metastasis is important to save the patient an unnecessary enucleation.[156]

Diagnostic Imaging

Although uveal melanomas can be accurately diagnosed by ophthalmoscopy, fluorescein angiography, or ultrasonog-

VIEW IMAGE

FIGURE 8-78 Malignant melanoma of the choroid. Axial CT scan shows a mushroom-shaped mass with increased density in the temporal quadrant of the left globe (*arrowheads*). (From Mafee MF et al. Malignant uveal melanoma and similar lesions studied by CT. Radiology 1985;156: 403–408.)

raphy, misdiagnosis continues to occur, particularly when opaque media preclude direct visualization.[137, 162–164] CT has proven to be a highly accurate method for demonstrating uveal melanoma, and dynamic CT can provide information about the vascularity and perfusion of intraocular lesions and can help distinguish uveal melanomas from other lesions such as choroidal hemangiomas. Most uveal melanomas are seen on CT as an elevated, hyperdense, sharply marginated lenticular or mushroom-shaped lesion (Figs. 8-78 and 8-79A).

MR imaging has been used to diagnose intraocular lesions.[21, 32, 165] On T1-weighted and proton density images, uveal melanomas are seen as areas of moderately high signal (greater signal intensity than in the vitreous) (Fig. 8-79B top). On T2-weighted images, melanomas are seen as areas of moderately low signal (lesser intensity than in the vitreous) (Fig. 8-79B bottom). These MR characteristics of uveal melanomas are very similar to those of retinoblastomas (Fig. 8-80). Associated retinal detachment is better visualized by MR imaging than by CT (Fig. 8-81). Exudative retinal detachment is usually depicted on MR imaging as a dependent area of moderate to very high signal intensity in T1-weighted, proton density, and T2-weighted images (Figs. 8-79 and 8-81), and total retinal detachment may be present. Chronic retinal detachment and hemorrhagic subretinal fluid have varied MR imaging appearances. Most uveal melanomas appear as a well-defined solid mass (Figs. 8-82 and 8-83). However, atypical features of ocular melanoma may be present. When necrotic or hemorrhagic foci are present within the uveal melanoma, the inhomogeneity present within the tumor can be problematic (Fig. 8-82). Some melanomas may be seen better on T1-weighted images (Fig. 8-82); discoid or ring melanomas may be difficult to detect if they are flat. Additionally, an organized subretinal exudate, with or without associated hemorrhage, may have MR characteristics similar to those of a uveal melanoma (Fig. 8-84). Tumor invasion of the sclera, optic disc, Tenon's capsule, and the extraocular orbit can be easily detected by MR imaging (Fig. 8-85). Paramagnetic contrast material is very useful in the diagnosis of uveal melanomas, in particular for evaluation of the optic nerve, as well as retrobulbar extension of ocular tumors (Fig. 8-86). Uveal melanomas demonstrate moderate enhancement on postgadolinium T1-weighted MR images. On fat suppression, the T1-weighted MR images demonstrate marked expansion of gray scale with apparently increased signal intensity of the extraocular muscles and lacrimal gland (Fig. 8-86C). Therefore, one should look carefully for extraocular tumor extension adjacent to the area of contact of extraocular muscles with the globe. Fat-suppressed T1-weighted MR images are prone to artifacts related

to dental fillings or other foreign bodies around the orbit (Fig. 8-87).

Choroidal lesions elevated more than 3 mm are usually well visualized on MR imaging. Any lesion less than 3 mm is better studied with ultrasound.[21, 32] The MR imaging characteristics of melanotic lesions are believed to be related to the paramagnetic properties of melanin.[166–168] Damadian et al. reported that, unlike other tumors, melanomas have short T1 relaxation times, which the authors attributed to paramagnetic proton relaxation by stable radicals in melanin.[166] Electron spin-resonance studies have shown that melanin produces a stable free radical signal under all known conditions, and these stable radicals cause proton relaxation enhancement that shortens both T1 and T2 relaxation time values.[167] However, a recent study[169] has shown that with the use of synthetic models, the content of free radicals in melanin (10^{18} spins per gram or one free radical per 3000 subunits), at the average concentration of melanin estimated within melanoma tissue (15 mg/ml), is too low to affect substantially the tissue TI relaxation time.[169]

It has been shown that melanin has a high affinity and binding capacity for metal ions,[169] and natural melanin contains a wide variety of bound metals in vivo (iron,

FIGURE 8-84 Malignant uveal melanoma and postradiation retinal detachment simulating recurrent tumor. **A**, Axial PW MR images show hyperintense masses (*arrows*). **B**, Axial T2-weighted MR images show hypointense masses. The eye was enucleated, and masses were found to be caused by highly proteinaceous, organized subretinal fluid with some degree of hemorrhage as well. The uveal melanoma was seen as a small, partially necrotic lesion. The MR imaging appearance of these subretinal changes is identical to the MR imaging characteristics of melanotic lesions. Therefore, caution must be exercised in MR imaging interpretation of intraocular lesions. When highly proteinaceous lesions are present, such as in this case or in the case of mucin-producing metastatic adenocarcinoma, MR imaging may not differentiate them from uveal melanomas.

copper, manganese, and zinc).[62] This indicates that melanin may have a cytoprotective function as an intracellular scavenger of free metals. The work of Enochs and associates[169] revealed that it is the binding of paramagnetic metals (paramagnetic metal scavenging) that is responsible for the high signal intensities of melanomas on T1-weighted MR images. Uveal melanomas therefore are unique in that both T1 and T2 relaxation values are relative shortened. Hence, on T1-weighted images, the lesion should be relatively hyperintense, the opposite of that predicted for T2-weighted images, and these signal intensities have been observed in the overwhelming majority of uveal melanomas. At times, uveal melanomas may have mixed or high signal intensity on T2-weighted scans (Fig. 8-83). The MR imaging diagnosis of uveal melanomas is greatly enhanced by the use of gadolinium contrast material. Uveal melano-

mas show moderate enhancement (Figs. 8-86 and 8-87), and ocular and extraocular invasion can be easily detected on postcontrast, fat-suppressed, T1-weighted scans. Extension into the orbit of a primary ocular melanoma is not common. The size of the extraocular extension is independent of the size of the ocular tumor (Fig. 8-85).

Differential Diagnosis

A number of benign and malignant lesions of the eye may be confused with malignant uveal melanomas. These conditions include metastatic tumors (Fig. 8-88), choroidal detachment, choroidal nevi, choroidal hemangioma, choroidal cyst, neurofibroma and schwannoma of the uvea,

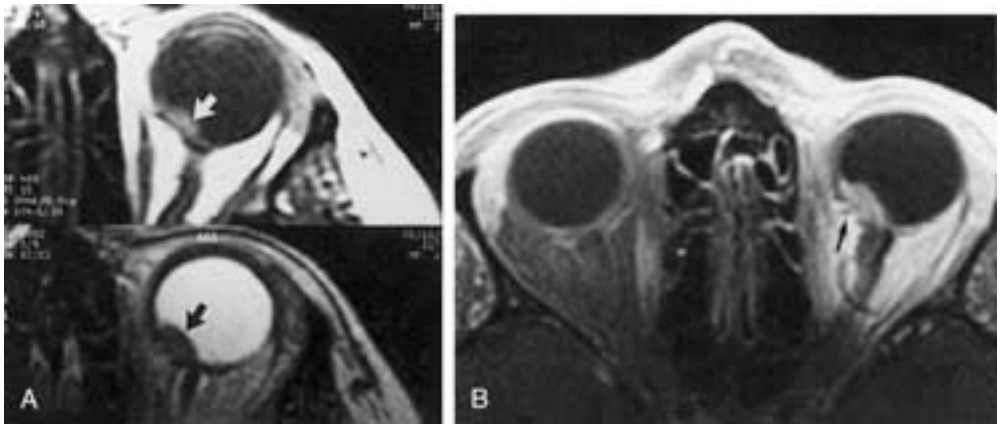

FIGURE 8-87 Malignant uveal melanoma. **A**, Axial T1-weighted (top) and T2-weighted (bottom) MR images showing a choroidal melanoma (*arrows*). **B**, Enhanced, fat-suppressed, T1-weighted MR image showing moderate tumor enhancement. Note the irregularity of the scleral and tumor nodule (*arrow*) caused by scleral invasion and retrobulbar extension, confirmed on histologic examination. The hyperintensity of the retrobulbar fat on the left in this image is due to dental metallic filling, causing a problem in suppressing the fat. (Courtesy of M.F. Mafee, MD, FACR, Chicago.)

leiomyoma, choroidal lymphoma (Fig. 8-89), adenoma of the ciliary body, medulloepithelioma, retinal detachment, and disciform degeneration of the macula.[19, 170, 171] The most important lesions in the differential diagnosis of iris melanomas and choroidal and ciliary body melanomas are listed in Tables 8-7 and 8-8.

Melanocytoma

Melanocytoma is a deeply pigmented benign tumor that usually occurs at the optic disc but may also arise anywhere in the uvea. Iris melanocytomas are rare and have a predisposition to release pigment into the anterior chambers, which causes a secondary open-angle glaucoma. Approximately 50% of melanocytomas develop in blacks, whereas the incidence of malignant uveal melanoma in blacks is less than 1%.[150] The MR imaging appearance of melanocytoma is similar to that of malignant uveal melanoma (Fig. 8-90). Melanocytomas are special types of uveal nevus. Melanocytoma of the optic disc usually is composed entirely of maximally pigmented, polyhedral nevus cells (magnocellular nevus cells).[40] Clinically, the lesion is a dark tumor that involves the substance of the optic disc. The melanocytomas appear homogeneously very hypointense on T2-weighted MR images (Fig. 8-90). Primary malignant melanoma of the optic nerve head is an exceedingly rare tumor.[172] Most melanomas of the optic nerve head are related to extension of a peripapillary choroidal melanoma.[173] The tumors are found to involve the choroid adjacent to the optic disc. Figure 8-91 shows a clinicopathologically proved primary malignant melanoma of the optic disc without choroidal involvement. The clinical appearance simulated that of a melanocytoma so precisely that the proper diagnosis was delayed. MR imaging demonstrated a discoid mass with

involvement of the optic nerve (Fig. 8-91), and the patient underwent enucleation of the right eye. Even though 17 mm of nerve was obtained, tumor was present at the point of surgical resection. Later, the patient underwent right frontotemporal craniotomy to remove the remainder of the optic nerve to the chiasm.

Uveal Metastasis

Uveal metastasis can be confused with uveal melanoma both clinically and on imaging. Metastatic lesions of the uvea extend chiefly in the plane of the choroid, usually with relatively little increase in thickness. Unlike uveal melanomas, which tend to form a protuberant mass, metastatic lesions have a mottled appearance and a diffuse outline, causing relatively little increase in their thickness.[62] The malignant cells (emboli) obtain access to the eye via the bloodstream by means of the short posterior ciliary arteries, and this may be the reason that the majority of metastases occur in the posterior half of the eye. The most common source of secondary carcinoma within the eye is from the breast or lung. Tumor metastasis may occur in both the retina and the choroid, both eyes being affected in about one-third of the cases. Unlike uveal metastasis, bilateral uveal melanomas are rare. Metastatic carcinoma of the pancreas and stomach also have been reported in the retina.[62] On CT, uveal metastasis may be difficult to differentiate from uveal melanoma.[19, 62, 174] MR imaging has been shown to be superior to CT in differentiating uveal metastasis from uveal melanoma.[19] However, uveal metastases may have signal characteristics similar to those of uveal melanomas (Fig. 8-92). Metastatic lesions of the choroid may lead rapidly to prominent and widespread detachment of the retina. In these patients, the mottled appearance and diffuse outline of the lesion may be rather different from those of uveal melanoma. Gd-DTPA has increased the sensitivity of MR for detection of uveal metastasis (Fig. 8-89). A mucin-producing metastatic lesion (adenocarcinoma) may also simulate a uveal melanoma because the proteinaceous fluid tends to decrease the T1 and T2 relaxation times of the lesion. We have seen metastatic carcinoid as well as hypernephroma that were indistinguishable from other uveal metastasis on MR imaging.

Uveal Nevus

Uveal nevi are congenital lesions, usually recognized late in the first decade of life and most frequently located in the posterior one third of the choroid.[40] Most choroidal nevi are less than 5 mm in basal diameter and less than 1 mm in thickness, but occasionally lesions of this type attain a basal diameter of 10 mm or more and a thickness of 3 mm or more.[40] They appear clinically as a flat or minimally elevated slate-gray choroidal mass with slightly indistinct margins. The color of these lesions depends largely on the composition of cell types within the nevus. Occasionally, choroidal nevi may be associated with shallow serous retinal detachment, with or without subretinal neovascularization.[168, 175, 176] If the macula becomes involved, this may cause visual field defects with decreased vision.[176] Under such circumstances, a choroidal nevus may simulate a choroidal melanoma both ophthalmoscopically and angiographically. The choroidal nevus is one of the most commonly misdiagnosed lesions to be enucleated under the misdiagnosis of malignant melanoma.[163, 164, 170] It is sometimes extremely difficult to differentiate these two lesions, with long-term follow-up being the only possible solution.[176] Most of the important lesions in the differential diagnosis of uveal nevi include melanoma of the iris, ciliary body, and choroid, metastatic carcinoma to the uvea, inflammatory granuloma, leiomyoma of the iris and ciliary body, juvenile xanthogranuloma of the iris and ciliary body, circumscribed choroidal hemangioma, choroidal osteoma, choroidal neurilemoma, subretinal or suprachoroidal hematoma, and foreign body in the iris.

Diagnostic Imaging

CT and MR imaging studies of several patients in whom uveal nevus was considered the likely ophthalmoscopic diagnosis showed that many lesions could not be visualized because of their small size, with most uveal nevi being less than 2 mm. In two uveal nevi seen on CT and MR imaging, the appearance was identical to that of uveal melanoma. Both of these patients underwent internal eye wall resection of the lesions, and a histopathologic study led to a diagnosis of choroidal nevus. It should be emphasized that CT and MR imaging are unable to differentiate uveal nevi from uveal melanomas. Internal eye wall resection may provide an alternative approach for suspicious lesions near the posterior pole, and this procedure has the advantage of preserving the globe.

Choroidal and Retinal Hemangiomas

Choroidal hemangiomas are seen usually in association with Sturge-Weber disease (encephalotrigeminal syndrome). Retinal angiomas (angiomatosis retinae), on the other hand, are seen in patients with von Hippel-Lindau disease. The diagnosis of choroidal hemangiomas on clinical grounds presents some difficulty. In the majority of cases, the lesion is discovered in the course of a pathologic examination, and in cases where an ophthalmoscopic examination had been performed, the tumor was concealed by the detachment of the retina.[177] The diagnosis of angiomatosis retinae of von Hippel-Lindau disease, by contrast, is chiefly dependent on the ophthalmoscopic appearance of the lesion. Sturge-Weber disease and von Hippel-Lindau disease belong to the general class of disorders referred to as phakomatoses. The major syndromes include neurofibromatosis, tuberous sclerosis (Bourneville's disease), encephalotrigeminal syndrome (Sturge-Weber disease), cerebelloretinal hemangioblastomatosis (von Hippel-Lindau disease), and ataxia-telangiectasia (Louis-Bar disease).

Sturge-Weber disease consists of capillary or cavernous hemangiomas that have a cutaneous distribution along the trigeminal nerve and of a predominantly venous hemangioma of the leptomeninges.[177, 178] The intracranial or cutaneous lesions may occur separately. The most familiar manifestation takes the form of the port-wine stain, or capillary nevus of the face, varying in its extent and sometimes being limited to the skin of the eyelids and conjunctiva. The eye changes are usually ipsilateral to the changes elsewhere, may be bilateral, and may be found without any surface angiomas. The ophthalmic changes consist of an angioma of the choroid, buphthalmos, or chronic glaucoma with atrophy and cupping of the optic nerve.[62, 177] The glaucoma may be explained by the angiomatous changes in the ciliary body or the angle of the anterior chamber.

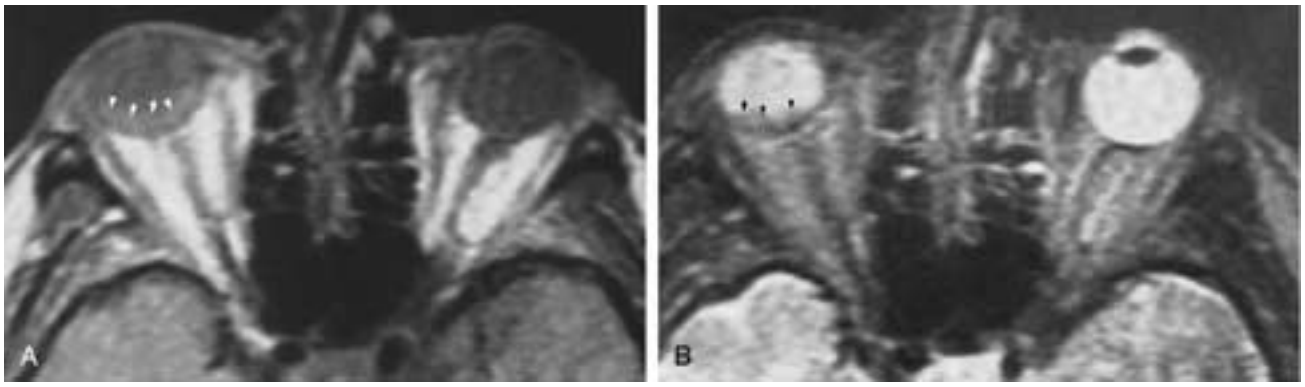

FIGURE 8-92 Choroidal metastasis. **A**, Axial PW MR image shows a hyperintense lesion (*arrows*) consistent with an ophthalmoscopic finding of choroidal metastasis. Note the irregularity of the lesion's surface. **B**, The lesion remained slightly hyperintense in this axial T2-weighted MR image.

Choroidal hemangiomas are congenital vascular hamartomas that are typically seen in middle-aged to elderly individuals, although they can be seen in children. Two different forms have been reported: (1) a circumscribed or solitary type not associated with other abnormalities and (2) a diffuse angiomatosis often associated with facial nevus flammeus or variations of Sturge-Weber syndrome.[62]

Clinical Features

Uveal hemangiomas are classified histologically into three descriptive categories: (1) cavernous, (2) capillary, and (3) mixed type. Regardless of their histologic classification, these lesions follow two major growth patterns: (1) the solitary circumscribed choroidal form and (2) the diffuse form associated with Sturge-Weber syndrome. Solitary choroidal hemangioma is confined to the choroid, shows distinct margins, and characteristically lies posterior to the equator of the globe.[62, 177] It is typically seen as a focal reddish orange choroidal tumor located in the juxtapapillary or macular regions of the fundus. In contrast, the hemangioma associated with Sturge-Weber syndrome is a diffuse process that may involve the choroid, ciliary body, iris, and occasionally other nonuveal tissues such as the episclera, conjunctiva, and limbus.

Diagnostic Imaging

Although uveal hemangiomas can be diagnosed by ophthalmoscopy, fluorescein angiography, or ultrasound, the clinical diagnosis may be difficult.[62, 177] In recent years, increased awareness of the various lesions of the uvea that may mimic melanoma (pseudomelanomas), combined with CT and MR imaging, has greatly decreased the frequency of erroneous diagnosis, so fewer eyes with choroidal hemangioma are enucleated.[62] A choroidal hemangioma is seen on plain CT as an ill-defined mass (Fig. 8-93A) that demonstrates marked enhancement with contrast infusion (Fig. 8-93B,C) and on dynamic CT (Fig. 8-93D). In some cases, the choroidal angioma may be concealed by the detachment of the retina (Fig. 8-93C). On MR imaging, a choroidal hemangioma may be seen as a hypointense area on T1-weighted (Fig. 8-93E) and T2-weighted images (Fig. 8-93F). Some choroidal hemangiomas are seen as a moderately intense area on T1-weighted, proton density, and T2-weighted images (Figs. 8-94 and 8-95). Whenever a choroidal hemangioma cannot be definitely differentiated from a uveal melanoma by MR imaging, contrast-enhanced CT is recommended using a combination of infusion-bolus (Fig. 8-93B) or dynamic CT techniques (Fig. 8-93D).[19, 36] Alternatively, gadolinium MR imaging may differentiate these entities (Fig. 8-95). The diagnosis of angiomatosis retinae of von Hippel-Lindau disease is chiefly dependent on the ophthalmoscopic appearance of the lesion. Because of the small size of the lesion (1.5 to 2 mm), retinal angiomas usually are not identified on MR imaging.

Angiomatosis Retinae and Von Hippel-Lindau Disease

Angiomatosis retinae and *von Hippel-Lindau disease* are interchangeable names for phakoma of the retinal angioma.[27] This syndrome consists of a vascular malformation of the retina and cerebellum. The retinal lesion usually has the characteristics of a malformation, and the cerebellar lesion consists of a slowly growing cystic hemangioblastoma(s). The cerebellar lesions may be multiple and associated with one or more spinal hemangioblastomas. Von Hippel described the ocular changes in 1895 and the clinical and pathologic changes in 1911. In 1926, Lindau described the frequent occurrence of von Hippel's ocular findings in patients with hemangioblastoma in the cerebellum, medulla, and spinal cord, with angiomas or cysts of the pancreas, liver, kidney, adrenals, epididymis, or ovaries.[27] This combination has been recognized as von Hippel-Lindau disease. Not all patients have a retinal lesion, the von Hippel part of the disease. Both eyes are affected in about 50% of cases, and 25% of the patients with retinal angioma manifest systemic involvement.[27, 40] Retinal angiomas are present at birth as hamartomatous collections of small nests of angioblastic and astroglial rest cells, but it is not until the second or third decade of life that an angioma grows sufficiently large to be clinically detected.[27] Among the conditions that must be considered in the differential diagnosis of angiomatosis retinae of von Hippel-Lindau disease are Eales' disease, Coats' disease, multiple retinal aneurysms (Leber's disease), and capillary angiectasis of the retina.[27, 40] Eales' disease, or retinal periphlebitis, occurs in young men (15 to 35 years old) and is characterized by vessel sheathing of the retina and vitreous hemorrhage. The retinal veins show sheathing with exudates, hemorrhage, and vasoproliferation.[40] There are also recurrent vitreous hemorrhages from affected veins.

Choroidal Hemorrhage and Choroidal Detachment

In discussing the differential diagnosis of uveal melanoma, choroidal hemorrhage and choroidal detachment must be considered because they may be easily mistaken for a choroidal tumor. A massive choroidal hemorrhage that has failed to rupture the lamina of Bruch may simulate the ophthalmoscopic, CT, and MR imaging appearance of a choroidal tumor because it forms a round, even globular, dark brown prominence that is opaque to transillumination (Figs. 8-96 and 8-97). The covering of the pigmented choroid, if the hemorrhage is in the suprachoroidal space, and of the retinal pigment layer may cause the hemorrhage's color to be even darker than that of the majority of melanomas. Such hemorrhage may become encapsulated and subsequently absorbed, leaving behind a more- or less-dense membrane. Choroidal effusion (uveal effusion) is another pathologic entity that can be confused with a ring melanoma.[53, 54] The CT and MR imaging appearances of choroidal hemorrhage (Figs. 8-41 and 8-97), choroidal detachment (Figs. 8-40, 8-46, and 8-47), uveal effusion (Fig. 8-48), were discussed earlier in this chapter.

Choroidal Cyst

Choroidal cysts are very rare. However, they can be mistaken for a choroidal tumor. They may be bilateral, and they may cause retinal detachment. The cyst may be successfully treated by the removal of its fluid content.

FIGURE 8-94 Choroidal hemangioma. **A**, Sagittal PW MR image shows a hyperintense mass (*arrow*). **B**, Sagittal T2-weighted MR image shows that the mass remains hyperintense. Ophthalmoscopic findings were most compatible with hemangioma. This MR imaging appearance may be difficult to differentiate from retinal detachment. Combined clinical and MR imaging findings should help the clinician make the right diagnosis.

Other Tumors of the Uvea

Ocular Lymphoma

Primary non-Hodgkin's lymphoma involving the eye is a rare condition. Modern immunohistochemical analysis shows that primary lymphomas of the retina and central nervous system (CNS) are usually large B-cell lymphomas.[40] The number of primary lymphomas of the retina and CNS has increased because of patients with acquired immune deficiency syndrome (AIDS) and other causes of immunodeficiency.[40] In contrast to primary ocular lymphoma, secondary ocular involvement by a systemic malignant lymphoma manifests itself mainly as a uveal tumor. Most often, the disease presents initially with signs of uveitis. Primary lymphoma of the eye is typically bilateral. Primary lymphoma of the retina can masquerade as a corticosteroid-resistant chronic uveitis.[40] Extensive infiltration of the retina and optic nerve head may lead to coagulative necrosis. Many atypical presentations of intraocular lymphoma have been reported, including a hemorrhagic retinal vasculitis that mimics a viral retinitis.[40] A secondary glaucoma may be present. The most important differential diagnosis includes the majority of cases of granulomatous uveitis, particularly ones that involve the retina, such as toxoplasmosis.[40] Ocular lymphoma can be mistaken for choroidal tumor.[62] On MR imaging, ocular

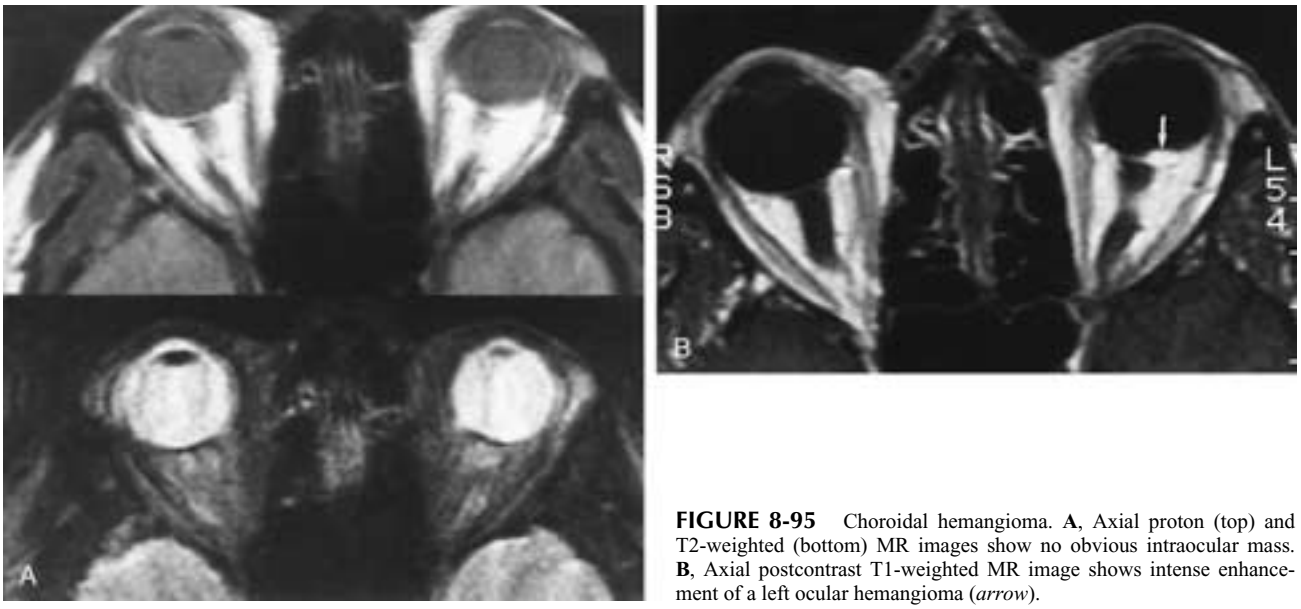

FIGURE 8-95 Choroidal hemangioma. **A**, Axial proton (top) and T2-weighted (bottom) MR images show no obvious intraocular mass. **B**, Axial postcontrast T1-weighted MR image shows intense enhancement of a left ocular hemangioma (*arrow*).

lymphoma may have signal characteristics similar to those of uveal melanomas (Fig. 8-98). They are often bilateral (Fig. 8-98). Bilateral melanomas are extremely rare.

Ocular Leukemia

Leukemic intraocular infiltration may involve the uvea, retina, optic disc, or vitreous. This is an uncommon ophthalmic disorder and unfortunately has a poor prognosis.[40] Leukemic intraocular infiltrates can present in one eye or both eyes. On MR imaging, leukemic infiltrates may have signal characteristics similar to those of uveal melanomas, metastasis, and intraocular inflammation (microbial and nonmicrobial).

Primary Ocular Schwannoma (Neurilemoma)

Primary ocular schwannoma is an extremely rare lesion that can cause diagnostic confusion with uveal melanoma. This benign neoplasm arises from the Schwann cells of the peripheral nerves in the uvea or sclera.[40] Primary ocular schwannoma occurs either in patients who have neurofibromatosis Type I or in patients who do not have this condition. It usually occurs as an amelanotic mass in the choroid or ciliary body that is indistinguishable clinically, by fluorescein angiography, and by ocular ultrasonography from a uveal melanoma.[40] The tumor consists of an encapsulated proliferation of amelanotic Schwann cells. Tumor cells exhibit positive immunoreactivity to S-100 protein but negative immunoreactivity to HMB-45 (melanoma-specific antigen) and muscle-specific markers (muscle-specific action).[40] The CT and MR imaging appearance of primary ocular schwannoma cannot be distinguished from that of uveal melanoma.[62] Primary intraocular neurofibroma is an extremely uncommon lesion that occurs in patients with neurofibromatosis Type I, although it has been reported in patients who have no manifestations of this syndrome.[40] The tumor is composed of an admixture of Schwann cells, fibroblasts, connective tissue, and neural axons and is usually nonencapsulated. The tumor typically arises in the choroid or ciliary body as an amelanotic mass that is indistinguishable from an amelanotic uveal melanoma by clinical examination and on imaging studies. At times in patients with neurofibromatosis Type I, the entire choroid may become thickened due to diffuse neurofibroma.

Leiomyoma

Smooth muscle tumors of the ciliary body are extremely rare and must be distinguished from other spindle-cell tumors, especially the more common amelanotic spindle-cell melanoma.[179, 180] Electron microscopic examination is necessary to prove the smooth muscle origin of these tumors.[179] Pathologically, leiomyoma consists of amelanotic spindle-shaped cells of benign appearance. Immunohistochemical staining shows positive immunoreactivity to muscle markers (muscle-specific action and smooth muscle action). Jakobiec et al.[180] reported two benign tumors of the ciliary body (one in a 37-year-old woman and another in a 20-year-old woman), which were diagnosed as neurogenic tumors by light microscopy but which on electron microscopic examination were found to be composed of smooth

muscle cells with unusual morphologic features. The authors concluded that myogenic and neurogenic characteristics reside in the neural crest origin smooth muscle of the ciliary body (mesectoderm) and that these tumors constitute a new nosologic entity of myogenic neoplasia. They coined the term *mesectodermal leiomyoma of the ciliary body* because the cells of the neural crest that contribute to the formation of bone, cartilage, connective tissue, and smooth muscle in the region of the head and neck have been called mesectoderm.[180] The MR appearance of a mesectodermal leiomyoma of the ciliary body has been reported.[84, 105] The lesion appeared as a well-defined noninfiltrative mass that demonstrated hyperintensity on T1-weighted, proton density, and T2-weighted images (Fig. 8-99). The CT and MR imaging appearance of ocular leiomyoma cannot be confidently distinguished from that of uveal melanoma and uveal neurogenic tumors.

Ocular Adenoma and Adenocarcinoma

Ocular adenoma and adenocarcinoma may arise from the pigment epithelium of the iris, ciliary body, or retina. Adenomas and adenocarcinomas of the ciliary epithelia appear as solid nodular lesions in the ciliary body region.[40] Those that arise from the pigmented ciliary epithelium are darkly melanotic, whereas those that arise from the nonpigmented ciliary epithelium are amelanotic. Ocular adenoma and primary adenocarcinoma are extremely rare tumors and may not be differentiated from ocular melanoma by CT and MR imaging.

Medulloepithelioma

Medulloepithelioma, or dictyoma, is a rare primary intraocular neoplasm derived from neuroectoderm, which characteristically arises from the primitive nonpigmented epithelium of the ciliary body.[40] Medulloepithelioma is usually seen in young children, although it can be seen in adults.[170, 181] Histologically, the tumor resembles embryonic retina and neural tissue.[181] This tumor has been divided into teratoid and nonteratoid types. The nonteratoid type (diktyoma) is a pure proliferation of cells of the medullary epithelium.[62] The teratoid type is distinguished by the additional presence of heteroplastic elements, particularly cartilage, skeletal muscle, and brain tissue.[62] Although most medulloepitheliomas are cytologically malignant, distant metastasis is uncommon.[62] From its point of origin on the ciliary body, the tumor may spread forward along the surface of the iris or backward along the surface of the retina.[62]

Medulloepithelioma generally occurs in the first decade of life as a nonpigmented ciliary body mass. In children, medulloepithelioma should be considered in the differential diagnosis of retinoblastoma, nematoid granuloma, and juvenile xanthogranuloma. In adults, this tumor may simulate amelanotic uveal melanoma and leiomyoma on ciliary body ophthalmoscopic evaluation, fluorescein angiography, ultrasonography, and CT (Fig. 8-100).[36] On MR imaging, medulloepithelioma appears similar to retinoblastoma and uveal melanoma.

Retinal Detachment in the Differential Diagnosis of Uveal Melanoma

The ophthalmoscopic appearance of a smooth globular outline of an elevated retina, characteristic of most cases of malignant uveal melanoma, on occasion may be caused by a simple retinal detachment. However, in practically all cases of simple retinal detachment, there is a retinal hole. On MR imaging, the appearance of a simple retinal detachment is characteristic, and provided that a mass is elevated more than 3 mm, the absence or presence of the mass can be readily assessed (Fig. 8-33). However, chronically organized or hemorrhagic subretinal fluid may have MR characteristics identical to those of uveal melanomas (Fig. 8-84).

Senile Macular Degeneration

Macular degeneration in the elderly is a leading cause of legal blindness. Arteriosclerosis of the choriocapillaries, dysfunction of the pigment epithelial cells, and loss of neuroepithelial cells are the fundamental causes of the macular degeneration syndrome in the elderly.[27] The earliest change at the macula is hyalinization and thickening of Bruch's membrane. Later, ingrowth of choroidal neovascularization into the subpigment epithelial space occurs, and eventually this results in detachment of the pigment epithelium. The serous fluid that accumulates in the subpigment space eventually finds its way into the subretinal space. One of the serious possible complications is hemorrhage, which is limited at first to the subpigment epithelial space but later extends into the subretinal space, eventually forming an organized fibrous scar, with consequent loss of almost all function of the involved macular.[27] The process of senile macular degeneration may be associated with liquefaction of the vitreous, which may cause posterior hyaloid detachment. The CT appearance of senile macular degeneration may be similar to that of uveal melanoma (Fig. 8-101). However, there may be more iodinated contrast enhancement in macular degeneration than in uveal melanomas. The MR imaging appearance of macular degeneration varies, depending on the stage of the disease. The lesion may show hyperintensity on all pulse sequences because of fluid in the subretinal space (Fig. 8-102), or there may be varied MR characteristics if there is associated hemorrhage and other complications (Fig. 8-102).

Ocular Trauma

Ocular trauma can be categorized as blunt or penetrating. Either mechanism can cause corneal tear, scleral rupture, lens dislocation, hemorrhage, retinal detachment, or choroidal detachment. Because of the pressure changes and radial distortions of the globe, blunt trauma may actually cause more damage to the eye than a small projectile passing through the globe.[182] There are imaging findings that may suggest many of the ocular injuries, but most are clinically obvious on clinical examination, and imaging is not usually ordered to assess these problems primarily. Ultrasound may

be used as part of an assessment, but the study is difficult to perform in the traumatized eye and is contraindicated in an open globe injury. Usually the most immediate concern for imaging is the possible presence of a foreign body, and the type of possible foreign body will determine the imaging modality used.

Intraocular foreign bodies (IOFBs) constitute a large percentage of ocular traumas, and advanced diagnostic and surgical techniques are required to manage them successfully.[183] Factors that influence the prognosis of IOFBs include the size, type of material, location, trajectory, reactivity, inflammatory response, degree and type of tissue damage, and length of time since the injury.

Patients presenting with ocular trauma are always examined for the presence of retained IOFBs. Indirect ophthalmoscopy, standard x-rays including the soft tissue (bone free) technique, CT, ultrasound, and, rarely, MR imaging are used to locate the foreign body. Localization of IOFBs is most often accomplished by CT, and this modality has proven valuable not only in detecting of IOFBs, but also in detecting ocular rupture (Fig. 8-103) and choroidal hematoma (Figs. 8-104 and 8-105).[52] Ultrasound is useful to examine the relationship of IOFBs to soft tissue pathology such as retinal detachment.[183]

The advent of endovitreal microsurgery has allowed a spectrum of treatment possibilities to be offered to the patient with a severely injured eye as well as for the removal of IOFBs. Therefore, a detailed diagnostic imaging study is vital to evaluate these patients properly. Of all ocular perforations, IOFBs occur in about 40%.[184] DeJuan et al.,[185] who reported a series of 453 cases seen at the Wilmer Eye Institute, found ocular perforations to be caused by projectiles (41%), lacerations (37%), and blunt trauma (22%). Of the 35 cases of IOFB studied by Coleman et al.,[183] 30 (86%) were due to metallic IOFBs; the remaining 5 (14%) consisted of three glass fragments and two concrete particles. Twenty-five of the metallic IOFBs proved to be magnetic. This means that magnetic IOFBs constitute 71% of all IOFBs and 83% of all metallic IOFBs. Three foreign bodies (8.5%) were due to BB guns. The high compressive and concussive forces seen in BB injuries are usually regarded as the reason for the poor prognosis.[183] The natural course of a retained IOFB varies widely. Small IOFBs may be completely resorbed,[186] and the IOFB may become encapsulated. Sederosis bulbi may develop in an eye with a retained iron-containing IOFB. The siderotic changes may stabilize or regress[187]; the foreign body may lose its magnetic properties or become radiolucent on x-ray.[187] Patients with a clinical diagnosis of siderosis bulbi may develop iris heterochromia, papillary mydriasis, cataract formation, retinal pigmentary degeneration, and occasionally optic disc hyperemia.[187] The diagnosis of IOFB is often made ophthalmoscopically or by slit-lamp examination. Gonioscopy will detect a foreign body in the anterior chamber angle. The removal of an IOFB should be strongly entertained in an eye with siderosis if a diminished electroretinographic response is noted or in an eye with a mobile foreign body in the vitreous or a nonencapsulated foreign body in the retina. Because up to 90% of IOFBs are magnetic,[183] the use of magnets has long been advocated for their removal. The magnets used in ophthalmic surgery

are of two general types: electromagnets and rare earth magnets.

Nonmagnetic IOFBs and even ferromagnetic foreign bodies are currently extracted in conjunction with posterior vitrectomy, endocoagulation, and removal of the foreign body by a forceps or other instrument. Retinal breaks may result from IOFBs. A retinal break encountered during vitrectomy generally is treated with retinopexy, often followed by fluid gas exchange and sometimes scleral buckling. Amber et al.[188] suggested that retinopexy may be avoided for retinochoroidal injury from a posteriorly situated metallic IOFB when there is no associated retinal detachment. The avoidance of retinopexy and fluid gas exchange may decrease the risk of retinal detachment and periretinal macular fibrosis.[188] Intraocular gas is known to cause breakdown of the blood-retina barrier, a situation that is significant in the stimulation of proliferative vitreoretinopathy.[188] Retained IOFBs are associated with endophthalmitis in approximately 7 to 13% of cases.[189] The use of intravitreal antibiotics in high-risk injuries and the possible use of vitrectomy surgery may reduce the incidence and severity of endophthalmitis.[189] Mieler et al.,[189] based on their experience, recommended prompt evaluation and surgical removal of acute retained IOFBs.

The optimal CT evaluation of intraocular pathology may consist of contiguous 1.5 mm axial sections parallel to the canthomeatal line. Thin sections are particularly valuable when evaluating small foreign bodies. Coronal and sagittal orbital reconstructions are helpful in confirming the intraocular location of a foreign body, especially when it is peripherally located. Direct coronal scanning is the best means of evaluating suspected foreign bodies at the 6 or 12 o'clock position in the globe. Plastic IOFBs are better demonstrated at a narrow window width, as described for intraorbital wood fragments.[190, 191] The plastics have a wide range of CT attenuation values (−125 to +364).[192] Most of the plastics are polyethylene, polystyrene, and polystyrene mixtures, which are inexpensive plastics often found in cheap disposable products such as fireworks.

CT scanning may fail to detect retained nonmetallic foreign bodies, especially when they are composed of organic material such as plastic[193, 194] or wood.[195] Ultrasound has the disadvantage of being technically difficult to perform; usually it is contraindicated in an open globe, and it does a poor job of identifying IOFBs when more than one is present.[193] MR imaging is contraindicated in the presence of a metallic foreign body.[193] Lobue et al.[193] performed CT and MR imaging on 10 enucleated eyes with wood, glass, and plastic foreign bodies. MR imaging detected all eight of the IOFBs compared to seven of eight found by CT. The authors noted that in three cases utilizing CT and involving wood or radiolucent plastic foreign bodies, confusion existed regarding whether a foreign body or merely an air bubble was detected. The authors stated that if a CT scan is normal and has ruled out a metallic IOFB, MR imaging may be useful in detecting and localizing a small nonmetallic foreign body. Williamson et al.[196] inserted a variety of magnetic and nonmagnetic IOFBs in 15 eyes. MR imaging (performed with a low-field MR unit) was accurate in locating 11 of the 15 foreign bodies that were nonmagnetic. The two foreign bodies not detected were located in the suprachoroidal space, suggesting that as with CT scanning, foreign bodies located near the sclera are hard to detect. Small steel foreign bodies produced artifact obscuring all intraocular details. Using a low-field MR unit caused no intraocular injuries and was considered safe by these authors. However, higher field strength MR imaging units have been demonstrated to apply torque to ferromagnetic foreign bodies, which are then capable in both animals[195] and humans[197] of causing intraocular damage. In general, MR imaging is contraindicated in traumatized eyes with suspected ferromagnetic foreign bodies. For those patients with a remote history of traumatic foreign body to the eye or in those people with jobs in a high risk field such as metal lathe work, a high-resolution 1.5 mm thick CT scan of the orbits and a 5 to 10 mm thick CT study of the head are recommended to rule out the possibility of foreign bodies.[198] An MR imaging study may be recommended after CT has ruled out the presence of a magnetic (metallic) foreign body.

Lagouros and associates[195] conducted in vitro and in vivo experiments to study MR imaging of IOFBs. Diamagnetic and paramagnetic foreign bodies were imaged without artifact and without movement during the imaging process, while ferromagnetic foreign bodies, as expected, produced large amounts of artifact that prevented meaningful imaging. All ferromagnetic foreign bodies moved during in vitro imaging. During in vivo imaging, three of four ferromagnetic foreign bodies moved, producing substantial retinal injury.

In general, all substances are influenced by a magnetic field, and their behavior in it is determined by their magnetic susceptibility according to the following equation:

$$X = \frac{\text{Intensity of Magnetization}}{\text{Magnetic Force}}$$ [199]

If X is negative, the substance is said to be diamagnetic; if X is positive, the substance is considered paramagnetic. In diamagnetic materials, the molecular currents (caused by electrons revolving in their orbit around their parent nuclei) in one direction are equal to those in the other direction. In the absence of an external field, the molecules of these substances have no net magnetic moment.[195] Paramagnetism occurs when the molecules of a substance have a permanent magnetic movement. A magnetic field acts on a molecule by aligning it with the external field and adding the molecular field to the external field. When an insulated wire is wound around a ring of any substance and an electrical current is passed through this system, a magnetic field is generated. With paramagnetic substances, this field is greater than that of the current in the winding alone. This field is 100 to 1000 times greater in a subclass of paramagnetic substances known as ferromagnetic substances. At room temperature, iron, nickel, cobalt, and gadolinium are the only ferromagnetic elements.[195] Alloys containing these elements also may be ferromagnetic.

The CT appearance of various plastics has been described by Henrikson and associates.[192] The authors concluded that plastics may not be readily apparent on a CT scan when they are small and in the negative CT number range (<−30 HU). Lagouros and associates[195] were able to image polystyrene with MR imaging, which had a CT density of −35 HU in the study by Henrikson et al.[192] It would seem that all plastics, being relatively hydrogen poor, have a signal void on MR

images, especially when they are in a relatively hydrogen-rich vitreous.[195]

The detection of an intraorbital wooden foreign body is difficult, particularly in cases of apparently minor trauma.[200–204] Orbital x-rays rarely detect wooden fragments.[203] CT has been shown to detect intraorbital wood associated with metallic paint[205] or a granuloma.[206] Wooden orbital foreign bodies are seen on CT scans as a site of low density; they often are mistaken for air or partial volume averaging of orbital fat. Both experimental[207] and clinical[208] studies have shown that CT has little value in detecting dry wood alone. Tate and Cupples[207] found that the high-resolution CT scanner could not detect small pieces of wood. Myllyla et al.[208] reported that CT scanning did not detect intraorbital wood in their two patients. They noted that the CT density of wood ranged from −618 to +23 HU. Orbital ultrasound also has some limitation in detecting intraorbital wood.[209] Intraorbital wooden foreign bodies are seen on MR imaging as an area of low signal intensity on T1-weighted, proton density, and T2-weighted images. They are particularly well delineated in T1-weighted MR images.[200] The usefulness of MR imaging in detecting orbital wooden foreign bodies was first reported by Green et al.[200] The authors recommended that MR imaging be done in all cases where orbital penetration by a wooden foreign body is suspected and the CT scan has not shown a foreign body. The possibility of an IOFB should be suspected in any patient sustaining minor lid trauma, especially when there is a history of injury caused by a pointed object. Second, if orbital fat is seen on direct physical examination, indicating violation of the orbital septum, an IOFB must be excluded. If standard x-rays and CT scans reveal a radiolucent focus anywhere within the orbit, particularly in a linear configuration, within the setting of orbital trauma, there should be a high index of suspicion for an organic foreign body.[210]

Globe Injury

The globe can be torn by penetrating injury or by blunt trauma. A projectile can perforate the globe or simple compression of the globe can cause tears in weak areas.[182] Pressure waves transmitted through the globe contribute to injury to the retina and choroid. In blunt trauma, the globe is usually compressed posteriorly, diminishing the anterior-to-posterior dimension. When this happens there is transient radial expansion at the equator followed by rebound in all directions.[182] This rapid variation in shape can tear the globe wall at various weak points. There can be vitreous extrusion and collapse of the globe. The sclera will fold inward, giving a wrinkled grape or ''crenated'' globe appearance (Figs. 8-106 to 8-108). More minor injuries can cause loss of pressure limited to the vitreous compartment or the aqueous chamber, and the aqueous chamber may appear less voluminous than normal (Fig. 8-109). There may slight distortion of the vitreous chamber. With slight loss of tone, the lens may appear to move slightly anteriorly or posteriorly, depending on the chamber involved.[211] In some cases, air is demonstrated in the globe and hemorrhage into the vitreous can be present. Of note, the globe may be normal in appearance; thus, imaging is not relied upon for exclusion of open globe injury or perforation of the globe.[212]

Hemorrhage into the eye is appreciated as increased density on CT. A hyphema, blood in the anterior chamber, may not be identifiable because the volume is small. Larger hemorrhages into the vitreous are more obvious. Hemorrhage may be seen as an isolated phenomenon or associated with wall rupture. Small foci of hemorrhage may mimic a foreign body. Retinal or choroidal detachments can be immediate or delayed. The retina can be torn by the acute injury, with hemorrhage pushing the retina away from the wall of the globe and into the vitreous compartment. Alternatively, injury to the vitreous can cause a fibrotic reaction, and subsequent retraction of scar can cause a delayed tractional detachment. Retinal and choroidal detachments were discussed earlier in this chapter.

The lens itself can be dislocated (Fig. 8-110; see also 8-106 and 8-107). With penetrating injury, the lens can be pushed directly into the vitreous cavity. In blunt trauma, the rapid changes in the shape of the globe can disrupt the zonule and suspensory fibers, destroying the supporting structure of the lens. In addition, the lens can be dislocated completely or can be dislocated along one margin if only a partial disruption occurs. The normal lens is a liquid crystal

structure with an extremely high protein content, and therefore is visible as a high density on CT contrasted against the vitreous. Any deviation from its normal position should suggest the possibility of zonular rupture with complete or partial dislocation. Patients with Marfan's syndrome are particularly prone to dislocations of the lens. Dislocations can be bilateral and can occur with minor trauma.

The lens capsule can be perforated. Fluid then moves into the lens, diluting the normally high protein (Fig. 8-111). On CT, the density decreases.[213–215] This decreased density represents early cataract formation. Later calcification can occur.

Avulsions of the extraocular muscles can give the appearance of a shorter, fatter muscle displaced or contracted posteriorly into the orbit. Because the sheath of the muscle may remain intact, a linear structure may remain, connecting the enlarged muscle belly to the globe. The optic nerve can also be torn or avulsed from the posterior globe.

Postsurgical Changes

Many surgical interventions result in a change in the appearance of the globe that is detectable on CT or MR imaging. Most of these findings relate to surgery for detached retina or cataracts.

Scleral buckle or banding, a procedure done for a detached retina, produces a very typical appearance.[216, 217] A plastic or composite band is placed completely around the equator of the globe, passing close to the insertion points of the rectus muscles (Fig. 8-112; see also Fig. 8-110). The inward ''squeeze'' decreases the likelihood that the retina will pull away from the wall of the globe once the retina has been reattached or reapproximated to its normal position. Most scleral buckles are made of silicone or hydrogel, are dense on CT, and have low signal intensity on MR imaging.[217] A silicone sponge can give the appearance of air and thus can be of low density on CT. The appearance of some materials can be variable, particularly on MR imaging, but the characteristic position of the buckle circling the globe usually makes the banding obvious. The inward ''girdling'' or bowing of the wall of the globe is also usually appreciable on imaging.

After the detached retina is repositioned against the wall of the globe, a laser or cryoprobe is used to fuse the retina to the more peripheral layers. The ophthalmologist may place a gas or fluid into the vitreous chamber to push the retina outward and tamponade the retina against the wall of the globe. Silicone oil, fluorosilicone oil, perfluorocarbon liquid, saline, and various other substances including expanding gases have been used for such tamponade retinopexy procedures. The appearance varies with the materials used.[217–220] Many materials are dense on CT and variable on MR imaging (Fig. 8-113). Some materials can be confused with diffuse hemorrhage if the history of previous surgery is not given. Silicone, for example, is dense on CT and has high signal intensity on T1-weighted images and low signal intensity on T2-weighted images.[221]

Probably the most common postsurgical change seen at imaging is the artificial intraocular lens (IOL) placed after cataract extraction. The lens is surgically removed via an incision in the sclera or a phacoemulsification is performed. In phacoemulsification, an instrument or probe is inserted into the lens, and ultrasound is used to disrupt and liquify the inner structure of the lens

including the cataract. The contents are then removed by suction. After either procedure, an IOL is then usually inserted.

With CT, rather than the biconvex structure characteristic of a normal lens, an IOL implant is typically seen as a thin, radiodense line (Fig. 8-107). A similar linear structure frequently can be appreciated on MR imaging. IOLs are commonly seen incidentally in patients undergoing imaging for nonorbital problems.

Finally, various drainage shunts and filters can be placed as decompression procedures in patients with glaucoma (Fig. 8-114), and the aqueous humor may collect in a reservoir-like ''bleb'' beneath the conjunctiva. Such a collection may be visible along the margin of the globe, usually close to the limbus.

Anophthalmic Socket and Orbital Implant

CT and MR imaging play an important role in the examination of the anophthalmic socket and the orbital implant.[222] There are two types of orbital implants: (1) spherical orbital implants, used following enucleation, and (2) reconstructive orbital implants, including plates, sheets, and fixation screws, which are used to repair nonsurgical and surgical trauma.[222] The spherical orbital implant is sutured within the intraconal space (Fig. 8-115). The layered closure includes the rectus muscles, Tenon's capsule, and the conjunctiva. An external custom-fit ocular prosthesis is then worn on the ocular surface (Fig. 8-115). Spherical orbital implants can be made of nonporous materials, such as silicone and polymethylmethacrylate, or of porous materials, such as porous polyethylene or hydroxyapatite (Fig. 8-116). Postenucleation imaging requests frequently involve such concerns as porous spherical orbital implant vascularization (Fig. 8-117), migration, exposure, orbital tumor recurrence, and associated craniofacial abnormalities.[222] Gadolinium-enhanced MR imaging has proven to be very valuable in determining the vascularization of hydroxyapatite implants following enucleation (Fig. 8-117).[223, 224] Based upon the extent of relative MR imaging enhancement within the implant, surgeons determine the appropriate time to integrate the spherical orbital implant surgically with an overlying external ocular prosthesis.[222–224] Integration involves drilling a hole through the overlying soft tissues into the spherical orbital implant and placing an integrational peg.[222] The peg, which is positioned inside the conjunctiva-lined hole is coupled with the external ocular prosthesis to improve motility.[222] A sufficient blood supply to the orbital implant must be present to support a conjunctival lining of the drilled interface.[222] Motility coupling pegs for porous polyethylene orbital implants recently have been introduced, and surgeons may request an MR study prior to placement of a peg.[225] MR documentation of fibrovascular ingrowth has broad clinical importance, and the rate of fibrovascular ingrowth is both patient and surgical technique dependent.[222]

EMBRYOLOGY OF THE ORBIT

The Orbit

The orbital bones develop from the mesenchyme that encircles the optic vesicle (see also the discussion of embryology in Chapter 8).[1, 2] The medial wall forms from the lateral nasal process. The lateral wall and inferior wall develop from the maxillary process. The superior wall forms from the mesenchymal capsule of the forebrain. The posterior orbit is formed by the bones of the base of the skull.[2] The bones of the orbit form as membranous bone, except for the ethmoid, which is enchondral in origin.[1, 2] It is interesting to note that early in development, the eye develops at a faster rate than the orbit, so that in the sixth month of fetal life the anterior half of the eye projects beyond the orbital opening. The eye increases rapidly in size during the first years of life. The rate of growth then slows but increases again at puberty. The cornea, which is relatively large at birth, reaches adult size by the time the child is 2 years old.[2] Pigmentation of the iris stroma occurs during the first years after birth.[2] The lens grows rapidly after birth and continues to grow throughout life. At birth the eye is hypermetropic (hyperopic or farsighted). Later, as the anteroposterior axis of the eye increases in length, this condition is corrected. A further increase in the anteroposterior axis could cause myopia, but generally this is prevented by the simultaneous flattening of the lens as growth proceeds.[2]

Extraocular Muscles

The extraocular muscles of the eye are formed from the mesenchyme in the region of the developing eye (preotic myotomes).[1] Originally represented as a single mass of mesenchyme, they later separate into distinct muscles, first at their insertions and later still at their origins. The levator palpebrae superioris is formed last, splitting off from the mesenchyme that forms the superior rectus muscle. During their development, the extraocular muscles become associated with the third, fourth, and sixth cranial nerves.[1]

The Eyelids

The eyelids develop as folds of surface ectoderm above and below the developing cornea (Figs. 9-1 and 9-2). As they grow, they become united with each other at about the third month of gestation.[1] The lids remain fused until about the fifth month of gestation, when they start to separate. Separation of the eyelids is completed by the seventh month of intrauterine life.[1] While the lids are fused, a closed space, the conjunctival sac, exists in front of the cornea. The mesenchymal core of the lids forms the connective tissue and tarsal plates. The mesenchyme of the second pharyngeal arch invades the eyelids to form the orbicularis oculi muscle supplied by the seventh cranial nerve. The cilia develop as epithelial buds from the surface ectoderm. The ciliary glands of Moll and Zeis grow out from the ciliary follicles. The tarsal glands (meibomian glands) develop as columns of ectodermal cells from the lid margins.[1] The epithelium of the cornea and conjunctiva is of ectodermal origin, as are the eyelashes and the lining cells of the tarsal and other glands opening onto the margins of the eyelids.[2]

The Lacrimal Gland

The lacrimal gland forms as a series of ectodermal buds that grow superolaterally from the superior conjunctival

fornix into the underlying mesenchyme.[1] These buds are arranged in two groups, one forming the gland proper and the other its palpebral process.[2] These buds later canalize, forming the secretory units and multiple ducts of the gland. The gland becomes divided into orbital and palpebral parts with the development of the levator palpebral superioris. Tears are usually not produced until 1 to 3 months after birth.

The Lacrimal Sac and Nasolacrimal Duct

The lacrimal sac and nasolacrimal duct initially develop as a solid cord of ectodermal cells in the nasomaxillary groove between the lateral nasal elevation and the maxillary process of the developing face.[1, 2] Later, this solid cord of cells sinks into the mesenchyme, and during the third month of embryonic life, the central cells of the cord break down and the cord becomes canalized to form the nasolacrimal duct. The superior end becomes dilated to form the lacrimal sac. Incomplete canalization, particularly in the lower end of the system, is common, even in full-term infants. Further cellular proliferation results in the formation of the inferior, superior, and common lacrimal ducts. The lacrimal canaliculi (superior and inferior) arise as buds from the upper part of the cord of cells and secondarily establish openings (puncta lacrimalia) on the margins of the lids.[2]

INTRODUCTION TO THE ORBIT

The orbits are two recesses that contain the globes, extraocular muscles, blood vessels, nerves (cranial nerves II, III, IV, V, VI and the sympathetic and parasympathetic nerves), adipose and connective tissues, and most of the lacrimal apparatus. The orbit is bordered by the periosteum of seven bones (frontal, sphenoid, ethmoid, lacrimal, maxilla, zygoma, and palatine), and it is separated from the globe by Tenon's capsule.[1, 3, 4] Anteriorly are the orbital septum and the lids. The orbital cavity is pyramidal in shape, with its apex directed posteromedially and its base, the orbital opening, directed anterolaterally. Its bony walls separate it from the anterior cranial fossa superiorly; the ethmoid air cells, sphenoid sinus, and nasal cavity medially; the maxillary sinus inferiorly; and the lateral face and temporal fossa laterally and posteriorly. The volume of the orbit in adult is about 30 cc. The orbital entrance averages about 35 mm in height and 45 mm in width, and the maximum width occurs about 1 cm behind the anterior orbital margin.[5, 6] In adults, the depth of the orbit varies from 40 to 45 mm from the orbital entrance to the orbital apex.

BONY ORBIT

Each orbit presents a roof, floor, medial wall, lateral wall, base (or orbital opening), and apex (Figs. 9-3 and 9-4). The orbital ventral margin or rim forms a quadrilateral spiral. The superior margin is formed by the frontal bone, which is interrupted medially by the supraorbital notch or foramen that transmits the supraorbital blood vessels and the supraorbital nerve, a branch of the ophthalmic division of the trigeminal nerve. The medial margin is formed by the frontal bone above and by the posterior lacrimal crest of the maxillary bone and the anterior lacrimal crest of the lacrimal bone below. The inferior margin is formed by the maxillary and zygomatic bones, while the lateral margin is formed by the zygomatic and frontal bones.

Orbital Roof

The orbital roof is formed from the orbital plate of the frontal bone and most of the lesser wing of the sphenoid bone (Fig. 9-3). Anteromedially is the floor of the frontal sinus, and anterolaterally is the lacrimal fossa, in which lies the orbital part of the lacrimal gland. Posteriorly, at the junction of the roof and the medial wall, are the optic canal and optic foramen (Fig. 9-4), which establish communication between the orbit and the suprasellar cistern and cavernous sinuses. The optic canal contains the optic nerve, ophthalmic artery, and sympathetic fibers. Medially and anteriorly is the fovea (fossa) trochlearis, which is located approximately 4 mm from the superior orbital margin. From it is formed the trochlea or pulley of the superior oblique muscle. The trochlea is a curved plate of hyaline cartilage attached to the trochlear fossa. Calcification of the trochlea is common.

Medial Orbital Wall

The medial wall is exceedingly thin, except at its most posterior part. This wall is formed by a small portion of the frontal process of the maxilla, the lacrimal bone, the ethmoid bone, and the body of the sphenoid (Figs. 9-3, 9-4). The medial wall slopes gently downward and laterally into the floor. Anteriorly is the lacrimal groove for the lacrimal sac. The groove communicates below with the nasal cavity through the nasolacrimal canal, which is about 1 cm long

VIEW IMAGE

and contains the nasolacrimal duct. The duct opens into the inferior meatus of the nasal cavity. Also in the medial wall are two canals for the anterior and posterior ethmoidal nerves and vessels. These canals are situated at the level of the floor of the anterior cranial fossa, as their lower margins are formed by the ethmoid bone and their upper margins are formed by the frontal bone. The anterior ethmoidal foramen is located at the frontal-ethmoidal suture and transmits the anterior ethmoidal vessels and nerve. The posterior ethmoidal foramen transmits the posterior ethmoidal vessels and nerve.[1, 3–6] If an external ethmoidectomy is performed and the surgeons keep their bone incision caudal to a line between these canals, the incision will be into the ethmoid complex and not into the anterior cranial fossa.

Orbital Floor

The inferior wall, or floor of the orbit, is relatively thin, and in most of its extent it is also the roof of the maxillary antrum or sinus (Figs. 9-3 and 9-4). The floor actually is made up of the orbital part of the maxilla, the orbital process of the zygomatic bone, and the orbital process of the palatine bone (Figs. 9-3 and 9-4). The orbital process of the palatine bone forms a small triangular area in the posteromedial corner of the orbital floor, where the floor meets the medial wall. The floor is not horizontal, but slants upward so that the posteromedial portion is higher than the flatter anterolateral portion.[1] Anteriorly, for about 1.0 to 1.5 cm, the floor is continuous with the lateral orbital wall. However, posterior to this area, the floor and lateral wall are separated by the inferior orbital fissure (Figs. 9-3 and 9-4). This fissure connects the orbit medially and posteriorly with the pterygopalatine fossa, and laterally and anteriorly with the retromaxillary and temporal fossae. The medial lip of the fissure is notched by the infraorbital groove, or fissure (Figs. 9-3 and 9-4), which passes forward in the orbital floor (usually in the middle third of the orbital floor), sinks into the orbital floor about 1 cm behind the orbital rim, and becomes the infraorbital canal that opens on

Copyright © 2003, Mosby, Inc. All rights reserved.

the anterior face of the maxilla as the infraorbital foramen, about 1 cm below the inferior orbital rim (Figs. 9-3 and 9-4).[1] The groove, canal, and foramen transmit the infraorbital nerve, the continuation of the maxillary nerve (V_2).[1, 3–6] The inferior oblique muscle arises from the floor of the orbit just lateral to the opening of the nasolacrimal canal.[5, 6] It is the only extraocular muscle that does not originate from the orbital apex.

Lateral Orbital Wall

The lateral wall of the orbit is the thickest wall, and it is formed by the orbital surface of the greater wing of the sphenoid bone behind and the orbital surface of the frontal process of the zygomatic bone in front (Figs. 9-3 and 9-4). The two bones meet at the sphenozygomatic suture. This aspect of the zygomatic bone presents the openings of two minute canals, one for the zygomaticofacial nerve and artery (near the junction of the floor and lateral walls) and the other for the zygomaticotemporal nerve and artery, which are slightly higher on this wall.[1, 5, 6] The lateral orbital tubercle, a small elevation of the orbital margin of the zygoma, lies approximately 11 mm below the frontal-zygomatic suture. This important landmark is the site of attachment for (1) the check ligament of the lateral rectus muscle, (2) the suspensory ligament of the eyeball, (3) the lateral palpebral ligament, and (4) the aponeurosis of the levator palpebrae muscle.[5, 6]

ORBITAL APEX

The apex of the orbit is basically formed by the optic canal and the superior orbital fissure.[1, 3] The optic canal and the superior and inferior orbital fissures allow various structures to enter and exit the orbit. The optic canal, having virtually no length at birth, becomes 4 mm long by 1 year of age and is up to 9 mm long in adults. The optic canal is directed forward, laterally (about 45° from the midsagittal plane), and somewhat downward (about 12° from the horizontal plane) and has orbital and intracranial openings (foramina). The configuration of the intracranial opening is oval, with its long axis in the horizontal plane. The configuration of the midportion of the optic canal is circular, and the configuration of the orbital opening is an oval with its long axis in the vertical plane. The optic canal is bounded medially by the body of the sphenoid bone (Figs. 9-5 and 9-6),

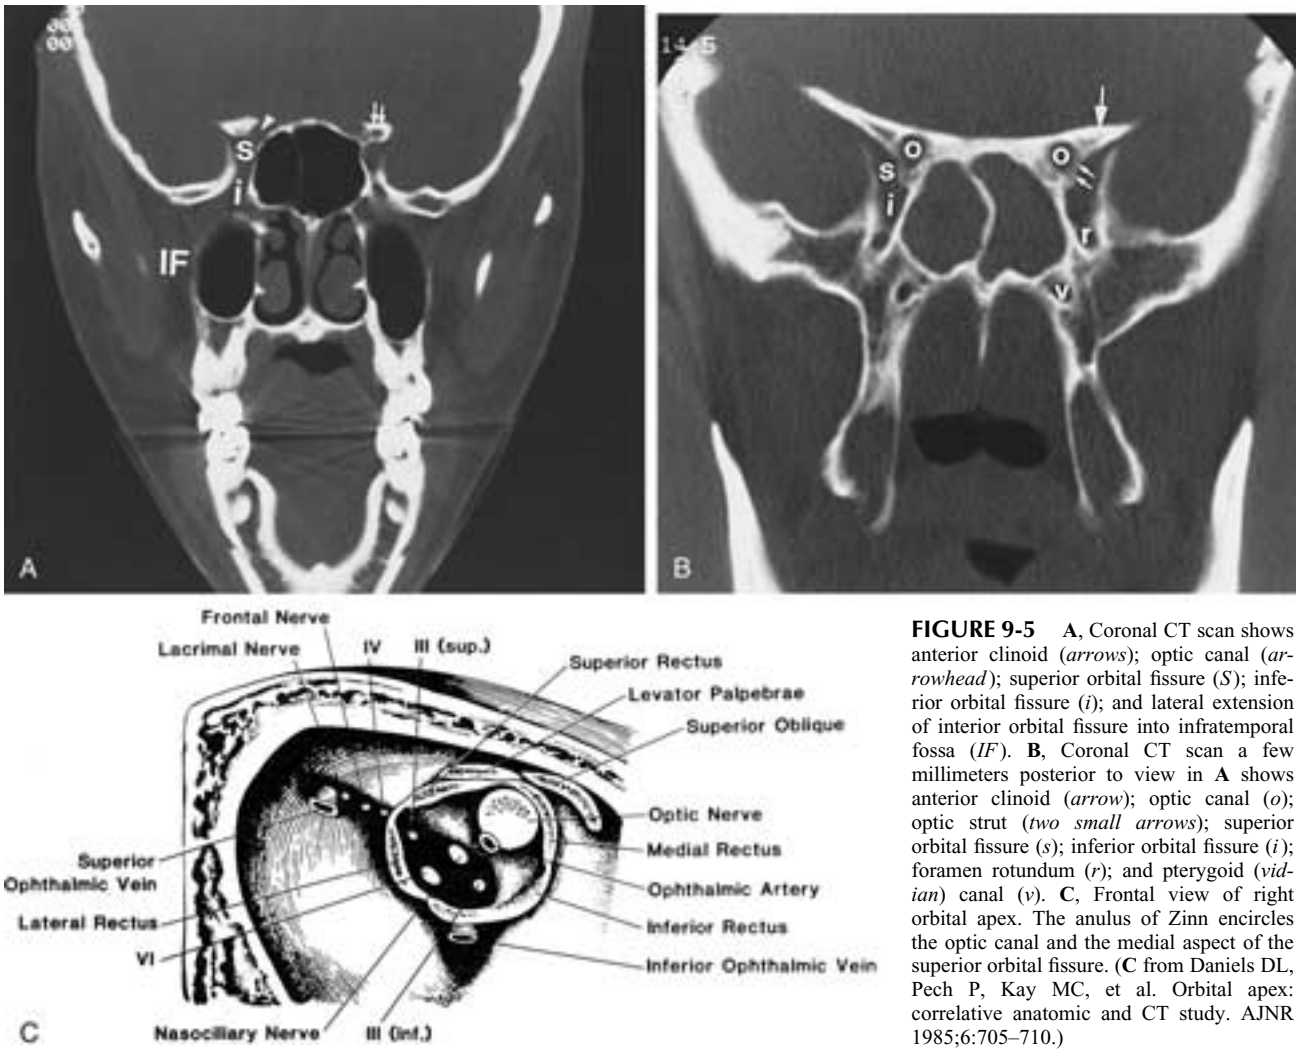

FIGURE 9-5 **A**, Coronal CT scan shows anterior clinoid (*arrows*); optic canal (*arrowhead*); superior orbital fissure (*S*); inferior orbital fissure (*i*); and lateral extension of interior orbital fissure into infratemporal fossa (*IF*). **B**, Coronal CT scan a few millimeters posterior to view in **A** shows anterior clinoid (*arrow*); optic canal (*o*); optic strut (*two small arrows*); superior orbital fissure (*s*); inferior orbital fissure (*i*); foramen rotundum (*r*); and pterygoid (*vidian*) canal (*v*). **C**, Frontal view of right orbital apex. FIGURE 9-6 Orbital CT anatomy. Direct parasagittal CT scan of cadaver head shows peripheral orbital space (*ps*); central orbital (intraconal) space (*CS*); optic nerve; superior rectus muscle (*S*) and inferior rectus muscle (*I*); inferior oblique muscle (*IO*); orbital septum (*curved arrow*); and common tendon of Zinn (*arrows*). Periosteum (periorbita) lines bony orbit as orbital fascia and is loosely attached to bony orbit. Periosteum is united with dura mater and sheath of optic nerve at optic canal. Normally, periosteum cannot be differentiated from adjacent soft tissues. Periosteum is continuous with periosteum of the bones of the face and is also continuous with layer of dura at superior orbital fissure. Note continuity of periorbita with periosteum of pterygomaxillary fossa (*PF*). Infection or infiltrative process of pterygomaxillary fossa may invade orbital subperiosteal space (periorbita) or vice versa. (CT scan courtesy of FW Zonneveld.) (From Mafee MF et al. Orbital space-occupying lesions: role of CT and MRI: an analysis of 145 cases. Radiol Clin North Am 1987;25:529.)

superiorly by the superior root of the lesser wing of the sphenoid bone, and inferiorly and laterally by the inferior root (optic strut) of the lesser wing of the sphenoid bone.[4] Attached to the orbital wall surrounding the opening of the optic canal (and thus the optic nerve, ophthalmic artery, and sympathetic nerves) and extending around the lower aspect of the vertical portion of the superior orbital fissure (encircling cranial nerves III and VI) is the common tendinous ring (annulus) of Zinn, which gives origin to the inferior, medial, lateral, and superior rectus muscles (Fig. 9-6).[1] Usually the inferior ophthalmic vein is below the annulus of Zinn in the lower aspect of the superior orbital fissure. Above the annulus of Zinn and within the superior orbital fissure are the superior ophthalmic vein, the recurrent meningeal artery, the lacrimal nerve, the frontal nerve, and cranial nerve IV.

Superior Orbital Fissure

Just inferolateral to the optic canal and separated from it by the optic strut is the superior orbital fissure, located between the greater and lesser wings of the sphenoid bone (Fig. 9-5). This fissure is approximately 22 mm long and is somewhat comma-shaped, with the bulbous or wider portion inferomedially and the thin portion superolaterally. The inferior part of the superior orbital fissure is divided from the superior part by the origin of the lateral rectus muscle.[1, 6] Where the fissure begins to widen, its lower border is marked by a bony projection, often sharp in character, which gives attachment to the lateral part of the common tendinous ring of Zinn. The superior orbital fissure communicates with the middle cranial fossa and transmits the oculomotor, trochlear, and abducens nerves and the terminal branches of the ophthalmic nerve (V_1) and the ophthalmic veins. The lacrimal, frontal, and trochlear nerves traverse the narrow lateral part of the fissure, which also transmits the meningeal branch of the lacrimal artery and the occasional orbital branch of the middle meningeal artery. The trochlear nerve is situated more medially and lies just outside the common tendinous ring of Zinn.[1] The two divisions (superior and inferior) of the oculomotor nerve, the nasociliary nerve (a branch of the ophthalmic nerve), the abducens nerve, and the sympathetic plexus pass within the tendinous ring and therefore traverse the wider medial part of the fissure. They may be accompanied by the superior and inferior ophthalmic veins, but the superior ophthalmic vein may also accompany the trochlear nerve, and the inferior ophthalmic vein may pass through the medial end of the fissure below the ring.[1]

Inferior Orbital Fissure

At the posterior aspect of the orbit, the inferior and lateral walls of the orbit are separated by the inferior orbital fissure (Figs. 9-3 to 9-5). The fissure lies just below the superior orbital fissure and is bounded above by the greater wing of the sphenoid, below by the maxilla and the orbital process of the palatine bone, and laterally by the zygomatic bone (the zygomaticomaxillary suture). The inferior orbital fissure extends obliquely as a gently curving continuation of the more medial pterygopalatine fossa (Figs. 9-6 and 9-7). The maxillary nerve is the most important structure traversing the inferior orbital fissure. The inferior orbital fissure also transmits the infraorbital vessels, the zygomatic nerve, and a few minute twigs from the pterygopalatine ganglion. Through the anterior part of the inferior orbital fissure, a vein passes to connect the inferior ophthalmic vein with the pterygoid plexus in the infratemporal fossa.[1] The inferior ophthalmic vein passes through its lower portion before entering the cavernous sinus.[6]

Pterygopalatine Fossa

The pterygopalatine fossa is a small, narrow pyramidal space situated below the apex of the orbit and tapering inferiorly[7] (Fig. 9-6). It is bounded above by the body of the sphenoid, in front by the maxilla, behind by the pterygoid processes and the greater wing of the sphenoid, and medially by the palatine bone (Fig. 9-6). It communicates with the infratemporal fossa through the pterygomaxillary (retromaxillary) fissure. The five foramina that open into this fossa are (1) the foramen rotundum, (2) the pterygoid (vidian) canal, (3) the pharyngeal (palatovaginal) canal (Fig. 9-5B), (4) the sphenopalatine foramen, and (5) the pterygopalatine canal. The most important contents of the fossa are the maxillary nerve, the pterygopalatine (sphenopalatine) ganglion, and the terminal part of the maxillary artery. The maxillary nerve (V_2) runs from the inferior aspect of the cavernous sinus and

Copyright © 2003, Mosby, Inc. All rights reserved.

exits the skull base through the foramen rotundum. The nerve then runs through the upper part of the pterygopalatine fossa, just above the pterygopalatine ganglion, and enters the inferior orbital fissure, passing forward and laterally to reach the posterior end of the infraorbital groove in the floor of the orbit. The nerve finally exits to the face through the infraorbital foramen.

Below and medial to the foramen rotundum, the pterygoid (vidian) canal (Fig. 9-5B) transmits the vidian nerve and vidian artery. The vidian nerve is formed by the joining of the superficial petrosal nerve (from the geniculate ganglion of the facial nerve containing parasympathetic and motor fibers) and the deep petrosal nerve, a branch from the sympathetic plexus on the internal carotid artery. The pterygoid nerve ends in the pterygopalatine ganglion.

The pharyngeal (palatovaginal) canal transmits the pharyngeal branch of the maxillary artery and the pharyngeal nerve, a branch of the pterygopalatine ganglion, to the roof of the pharynx. This nerve is distributed to the mucous membrane of the nasal part of the pharynx, behind the auditory tube.[1] The sphenopalatine foramen is on the medial wall of the pterygopalatine fossa. It is bounded above by the body of the sphenoid, in front by the orbital process of the palatine bone, behind by the sphenoidal process, and below by the upper border of the perpendicular plate of the palatine bone. It transmits the nasopalatine nerve and accompanying vessels from the pterygopalatine fossa to the nasal cavity.

VIEW IMAGE

The pterygopalatine canal extends from the inferior margin of the pterygopalatine fossa, at the junction of the anterior and posterior walls, to the greater palatine canal opening in the palate. The greater palatine canal transmits the greater (anterior) and lesser (middle and posterior) palatine nerves and the palatine vessels. In general, the pterygopalatine ganglion supplies parasympathetic innervation to the pharynx, palate, nasal cavity, and lacrimal gland.[4] Thus, in summary, the pterygopalatine fossa communicates with five major anatomic regions: (1) the nasal cavity via the pterygopalatine (sphenopalatine) foramen, (2) the oral cavity via the pterygopalatine canals, (3) the infratemporal fossa via the pterygomaxillary (retromaxillary) fissure, (4) the orbit via the inferior orbital fissure, and (5) the middle cranial fossa via the foramen rotundum and the vidian canal.

PERIORBITA

The periosteum of the bony orbit is known as the *periorbita* or the *orbital fascia*.[8] The periosteum is a specialized connective tissue structure that covers the bones. It consists of two strata: a superficial fibrous mantle and an active inner layer known as the *cambium*.[9] Duhamel is credited with the first scientific investigation of the osteogenic properties of the periosteum.[10] The periorbita (orbital fascia) is generally loosely adherent to the surrounding bones except at the anterior orbital margin, trochlear fossa, lacrimal crests, and margins of the fissures and canals.[1, 3, 4, 8] Anteriorly, it is continuous with the periosteum of the orbital margins (Figs. 9-6 to 9-8). Posteriorly, it is continuous with the dura of the optic nerve and the dura surrounding the superior orbital fissure. Thus, posteriorly located surgery or trauma may result in cerebrospinal fluid (CSF) leaks.[3] The dura matter is composed of a meningeal layer and a periosteal layer. These two layers are so closely bound together that they can be separated only with difficulty.[4, 7] After these layers pass through the optic foramen, however, they become separated. The meningeal layer continues as the sheath of the optic nerve, and the periosteal layer lines the bony orbit as the orbital fascia or periorbita. Numerous septae and fascial bands from various structures in the orbit are attached to the inner surface of this periosteum.[4] In front, the periorbita is fused with the orbital septum along the margins of the base (anterior rims) of the orbit.[5] The orbital septum is the continuation of the periosteum.[4, 8]

ORBITAL SEPTUM AND EYELIDS

The orbital septum is a thin sheet of fibrous tissue that forms the fibrous layer of the eyelids and is attached to the margins of the bony orbit, where it is continuous with the periorbita. In the upper eyelid, it fuses with the levator aponeurosis. In the lower eyelid, the orbital septum fuses with the capsulopalpebral fascia (see below) approximately 3 to 5 mm below the inferior tarsal border. The fused capsulopalpebral fascia/orbital septum complex, along with a small contribution from the inferior tarsal smooth muscle, inserts on both the posterior and inferior tarsal surfaces, as well as on the tapered inferior border of the tarsus.[5] The

palpebral portion of the orbicularis oculi muscle lies in front of the orbital septum (Fig. 9-8).[5] Moving from the skin inward toward the orbit, in general, each eyelid or palpebra consists of skin, subcutaneous areolar tissue, fibers of the orbicularis oculi, the tarsus and orbital septum, tarsal glands (meibomian), and conjunctiva. The conjunctiva is the transparent vascularized mucous membrane that covers the inner surfaces of the eyelids, and is reflected over the front part of the sclera and cornea.[1, 5] The line of reflection of the conjunctiva from the eyelids on the eyeball is called the *conjunctival fornix*. The palpebral conjunctiva is highly vascular, and its deeper part contains a considerable amount of lymphoid tissue, especially near the fornices. It is intimately adherent to the tarsi.[1] The ocular conjunctiva is loosely connected to the eyeball. On reaching the cornea, the ocular conjunctiva continues as the corneal epithelium.[1] The palpebral conjunctiva is covered by a nonkeratinized epithelium that contains the mucin-secreting goblet cells and the accessory lacrimal glands of Krause and Wolfring.[5] Secretions from these accessory glands form the major components of the lacrimal secretion, in contrast to the reflex tear secretion from the parasympathetically innervated main lacrimal gland.[5] Thus, anteriorly, the orbit can be considered as being closed by the orbital septum (Figs. 9-6, 9-8), which forms the fibrous layer of the eyelids. Within each eyelid, the orbital septum is thickened to form a tarsal plate. The levator palpebrae superioris has a broad anterior aponeurosis. Some of its fibers attach to the superior tarsal plate, while other terminal filaments interdigitate with the superior tarsal muscle (Müller's muscle), a smooth muscle that extends along the upper margin of the superior tarsal plate. As a result, some of the action of the levator palpebrae superioris must extend through Müller's muscle before it affects the superior tarsal plate. In Horner's syndrome, the ptosis associated with that syndrome occurs because Müller's muscle is paralyzed and the upper eyelid cannot be elevated until this muscle has been passively stretched out to its full length by the action of the levator palpebrae superioris. This results in end-stage ptosis and minimal lid elevation after the complete contraction of the levator palpebrae superioris. A few fibers of the inferior rectus muscle are attached to the lower edge of the inferior tarsal plate.[5, 6] Posteriorly, each plate is covered by conjunctiva and has meibomian glands (modified sebaceous glands) embedded in its deep surface.

The tarsal plates consist of dense connective tissue and serve as the skeleton of the eyelids. They are attached to the orbital margin by the lateral and medial palpebral ligaments. The length (22 mm) and thickness (1 mm) of the upper and lower tarsal plates are similar.[6] The upper tarsus is more than twice as wide (11 mm) as the lower tarsus.[6] The tarsal (meibomian) glands are modified sweat glands, and their oily secretion passes through small orifices into the tear film.

ORBICULARIS OCULI

The orbicularis oculi muscle is a flat, elliptical muscle that surrounds the orbital margin, extending onto the temporal region and cheek (orbital portion), onto the eyelids (palpebral portion), and behind the lacrimal sac (lacrimal portion) (Fig. 9-8). The palpebral portion of the orbicularis muscle consists of thin bundles of fibers that arise from the medial palpebral ligament (Fig. 9-8). The fibers sweep

laterally and concentrically across the eyelids and in front of the orbital septum. At the lateral angle of the eye, the fibers interlace at the lateral palpebral raphe.

TENON'S CAPSULE (FASCIA BULBI) AND TENON'S SPACE

Tenon's capsule is a fibroelastic membrane that envelops the eyeball from the optic nerve to the level of the ciliary muscle. Tenon's capsule is also called the *fascial sheath*, *fascia bulbi*, and *bulbar fascia* of the eyeball. This fibroelastic socket, which encloses the posterior four fifths of the eyeball, separates it from the central orbital fat (Figs. 9-6 and 9-8).[4, 8] Movement of the eyeball is facilitated by the fascia bulbi, which invests but does not adhere to the sclera. The bulbar fascia is discussed in Chapter 8.

ORBITAL FATTY RETICULUM

Within the orbit, all structures are embedded in a fatty reticulum. The fibroelastic tissue that makes up the reticulum divides the fat into lobes and lobules.[4–8] The fatty reticulum is divided into (1) peripheral orbital fat, which is outside the muscle cone and its intermuscular membranes (Figs. 9-4, 9-6, and 9-8), and (2) central orbital fat, which is within the muscle cone (Figs. 9-6 and 9-8).

EXTRAOCULAR MUSCLES

The six striated extraocular muscles, including the four recti and two oblique muscles, control eye movement (Figs. 9-6, 9-8). The rectus muscles arise from the annulus of Zinn, which is a funnel-shaped tendinous ring that encloses the optic foramen and the medial end of the superior orbital fissure, where it is continuous with the dural sheath of the optic nerve and periorbita.[3, 8–11] The annulus has an upper portion, called the *superior orbital tendon* or the *upper common tendon of Lockwood*, and a lower portion, called the *lower common tendon of Zinn*.[12] Because of this intimate relationship, apical disease frequently affects all of these structures simultaneously. In addition, surgical removal of optic nerve tumors must be done within the annulus, which is most safely entered superomedially after removing the orbital roof.[3] The inferior rectus muscle originates from the common tendon of Zinn below the optic foramen. It inserts into the inferior sclera 6.5 mm from the limbus. The superior rectus (the longest of the four recti) originates from the common tendon of Lockwood above the optic foramen and from the sheath of the optic nerve. It passes below the levator aponeurosis and inserts into the upper sclera 7.7 mm from the limbus. The medial rectus muscle (the thickest of the recti) arises from the upper tendon of Lockwood, the lower tendon of Zinn, and the sheath of the optic nerve and inserts 5.5 mm from the limbus.[11, 12] The lateral rectus originates from the lower common tendon of Zinn and the upper common tendon of Lockwood and inserts 6.9 mm from the limbus.[12] The superior oblique (longest and thinnest of the extraocular muscles) originates from the periosteum of the body of the sphenoid bone, above and medial to the annulus of Zinn and the origin of the medial rectus.[11, 12] It passes anteriorly along the upper part of the medial orbital wall as a slender tendon and enters the trochlea, a fibrocartilaginous ring lined with a synovial-type sheath.[13] The tendon slides through the trochlea and then turns sharply posterolaterally and downward beneath the superior rectus muscle to insert in the lateral sclera, behind the equator of the eye. The inferior oblique muscle is the only extrinsic eye muscle that originates not from the orbital apex but from a shallow depression in the orbital plate of the maxilla at the anteromedial corner of the orbital floor just posterolateral to the orifice of the nasolacrimal duct. It passes under the inferior rectus and runs posteriorly, laterally, and superiorly before inserting into the inferolateral aspect of the globe.[14] All extraocular muscles are about 40 mm in length except for the 37 mm inferior oblique.[15] One important difference among these muscles is the ratio of tendinous tissue to muscle fibers. The inferior oblique muscle contains essentially no tendon, and the superior oblique has 20 mm of tendon.[15]

Spiral of Tillaux

The four rectus muscles insert on the anterior portion of the globe in a configuration called the *spiral of Tillaux*.[6] The medial rectus muscle inserts closest to the limbus, and the superior rectus muscle inserts farthest from the limbus. The relationship between the muscle insertions and the ora serrata is clinically important, as a malpositioned bridle suture could pass through the insertion of the superior rectus muscle and perforate the retina.[6]

Retractors

The retractors of the upper eyelid are the levator muscle, the levator aponeurosis, and the sympathetically innervated superior tarsal muscle (Müller's muscle).[5] In the lower eyelid, the retractors are the capsulopalpebral fascia and the inferior tarsal muscle (Müller's muscle).[5]

Levator Muscle

The levator palpebrae superioris muscle originates in the apex of the orbit from the periorbita of the lesser wing of the sphenoid, just above the annulus of Zinn.[5] The body of the levator muscle overlies the superior rectus as it travels anteriorly toward the lid. The levator muscle and its tendon in adults is 50 to 60 mm long. The muscle portion, which is approximately 40 mm long, is innervated by the superior division of the oculomotor nerve and elevates the upper eyelid. The levator palpebra is often called the *seventh extraocular muscle*. The superior transverse ligament (Whitnall's ligament) is a condensation of the sheath of the levator muscle located in the approximate area of the transition from levator muscle to levator aponeurosis.[5] Whitnall's ligament functions primarily as a suspensory support for the upper eyelid and the superior orbital tissues.[5] Its analog in the lower eyelid is Lockwood's ligament.[5] As

Copyright © 2003, Mosby, Inc. All rights reserved.

the levator aponeurosis continues forward, it inserts into the anterior surface of the tarsus and by medial and lateral horns into the canthal tendons.[5, 6] The lateral horn of the levator aponeurosis is strong, and it divides the lacrimal gland into orbital and palpebral lobes, attaching firmly to the orbital tubercle.[5] As mentioned, the superior tarsal muscle (Müller's muscle) also inserts on the superior tarsal border, and this muscle provides approximately 2 mm of lift for the upper eyelid. If this muscle is paralyzed, as in Horner's syndrome, a mild proptosis will result.[5]

Lower Eyelid Retractors

The capsulopalpebral fascia is the lower eyelid analog to the levator palpebra muscle and aponeurosis.[5] It is a layer of dense connective tissue that originates at the capsulopalpebral head from the terminal muscle fibers and tendon of the inferior rectus muscle.[5] The capsulopalpebral head divides into two portions as it encircles and fuses with the sheath of the inferior oblique muscle. Anterior to the inferior oblique muscle, the two portions of the capsulopalpebral head join to form Lockwood's suspensory ligament, where it becomes known as the *capsulopalpebral fascia*.[5] The capsulopalpebral fascia fuses with the orbital septum. This fused fascial layer proceeds upward to insert on the inferior tarsus.[5]

Movements of Eyelid and Eyeball

The levator palpebra superioris is the main, striated voluntary muscle that elevates the upper eyelid. It is opposed by the orbicularis oculi.[1, 6] When the smaller inferior stratum of nonstriated Müller's muscle is denervated, it is responsible for the ptosis in Horner's syndrome. Blinking results in distribution of the lacrimal secretions. The height at which the upper lid is maintained is in part related to the brightness of the light entering the eye. In very bright conditions, the lid is lower, thereby limiting glare.

Within its fascial sheath, the eyeball is rotated by the extraocular muscles, which displace the gaze upward (elevation), downward (depression), medially (adduction), and laterally (abduction). Rotation about an anteroposterior axis (torsion) may also occur.[11, 12, 14, 15] The actions of the medial and lateral recti are adduction and abduction, respectively. They are antagonists, and by reciprocal adjustment of their lengths, the visual axis can be swept through a horizontal arc. The superior rectus muscle's primary action is elevation. This muscle also has a secondary, less powerful action of medial rotation (adduction).[1, 12] Its primary antagonist is the inferior rectus, which depresses and adducts the eyeball. The superior oblique muscle acts on the eyeball from the trochlea. Because the attachment of the inferior oblique is for practical purposes vertically inferior to this, both muscles approach the eyeball at the same angle, being attached in approximately similar positions in the superior and inferior posterolateral quadrants of the eyeball.[1] From these attachments, it is easy to understand that the inferior oblique elevates the gaze and the superior oblique depresses it. Both oblique muscles produce abduction.[1, 12] Like the superior and inferior recti, the two oblique muscles have opposed forces with respect to the other (antagonist). However, acting together, they can assist the lateral rectus in abduction of the visual axis.[1]

Blood Supply to the Extraocular Muscles

The blood supply for the extraocular muscles is derived from the inferior and superior muscular branches of the ophthalmic artery, the lacrimal artery, and the infraorbital artery. Except for the lateral rectus muscle, each rectus muscle receives two anterior ciliary arteries that communicate with the major arteriole circle of the ciliary body. The lateral rectus is supplied by a single vessel derived from the lacrimal artery.

OPTIC NERVE

The optic nerve is not a nerve but actually a nerve fiber tract of the central nervous system formed by over 1 million axons that originate in the ganglion cell layer of the retina.[6, 16] The nerve has an organization similar to that of the white matter of the brain. Its fibers are surrounded by glial rather than Schwann cell sheaths.[6, 16] The optic nerve (Fig. 9-6), along with the ophthalmic artery, traverses the optic canal and passes forward and laterally within the cone of rectus muscles to enter the eyeball just medial to its posterior pole. The optic nerve is about 3.5 to 5.5 cm long and about 3 to 4 mm in diameter.[3, 6] It is divided into four portions: intraocular (1 mm), intraorbital (3 cm), intracanalicular (5 to 6 mm), and intracranial (1 cm).[3] The intraocular portion can be divided into three parts: (1) prelaminar, (2) laminar, and (3) retrolaminar. The surface of the prelaminar portion is visible ophthalmoscopically. It is a 1.5×1.75 mm oval with a disc-shaped depression (the physiologic cup) located slightly temporal to its geometric center.[5, 6] The optic nerve head (optic disc) is composed of nonmyelinated axons from the retinal ganglion cells, blood vessels, and astrocytes that form a thin basal lamina on its inner surface. Myelinated nerve fibers in the retina result from oligodendrocytes that have migrated beyond the lamina cribrosa and have formed a lamellar envelope around ganglion cell axons.[5, 6] As ganglion cell axons enter the optic nerve head, they become segregated into bundles or fascicles by neuroglial cells. These astrocytes enclose groups of nerve fibers throughout the ocular and orbital portions of the optic nerve.[5] The bundles continue to be separated by connective tissue all the way to the chiasm. This connective tissue is derived from the pia mater and is known as the *septal tissue*.[5, 6] The retinal layers terminate as they approach the edge of the optic disc. The laminar portion of the optic disc is composed of astrocytes, elastic fibers, collagenous connective tissue from the scleral lamina, and small blood vessels. The lamina cribrosa functions as a scaffold for the optic nerve axons. The retrolaminar portion extends from the lamina cribrosa to the apex of the orbit. From the lamina cribrosa centrally, the retinal ganglion cells become myelinated as the cross-sectional diameter of the nerve increases to approximately 3 mm. After passing through the optic canal, the optic nerves lie above the ophthalmic arteries, and above and medial to the internal carotid artery. The anterior cerebral arteries cross over the optic nerves and are joined by

Copyright © 2003, Mosby, Inc. All rights reserved.

the anterior communicating artery. The optic nerves then pass posteriorly to join in the optic chiasm.

Meningeal Sheaths (Dura, Arachnoid, Pia)

The dura, the outer layer, is composed of collagenous connective tissue. The arachnoid is made up of fine collagenous fibers arranged in a loose meshwork lined by endothelial cells. The innermost layer, the pia, is made up of fine collagenous and elastic fibers and is highly vascularized. Elements from both the arachnoid and the pia are continuous with the optic nerve septa. The pial septa, which originate in the region of the posterior lamina cribrosa, enclose all neurofascicles. The septa continue throughout the orbital and intracanalicular portion of the nerve and end in the intracranial portion. They are composed of collagen, elastic tissue, fibroblasts, nerves, and small arterioles and venules. They provide mechanical support for the nerve bundles and nutrition to the axons and glial cells. Meningothelial cells cover the pia mater. The arachnoid mater is continuous with the subarachnoid space. It ends at the level of the lamina cribrosa. It is composed of collagenous tissue, small amounts of elastic tissue, and meningothelial cells. The dura mater encases the optic nerve and comprises the outer layer of the meningeal sheaths. It is 0.3 to 0.5 mm thick and consists of dense bundles of collagen and elastic tissue fused anteriorly with the outer layers of the sclera. The meninges of the optic nerve are supplied by sensory fibers, which accounts for the pain experienced by patients with inflammatory optic nerve diseases.

Blood Supply of the Optic Nerve

The prelaminar and lamina cribrosa regions are supplied by branches of the posterior ciliary arteries, while the surface of the optic disc is supplied by retinal arterioles that are branches of the central retinal artery or from branches of small cilioretinal arteries.[5, 6, 16] The intraorbital part of the optic nerve is supplied by intraneural branches of the central retinal artery and multiple recurrent pial branches arising from both the peripapillary choroid and the central retinal and ophthalmic arteries.[5] The intracanalicular portion of the optic nerve is supplied almost exclusively by the ophthalmic artery. The intracranial portion of the optic nerve is supplied primarily by branches of both the internal carotid artery and the ophthalmic artery. The actual distance from the back of the globe to the orbital apex is 20 mm. Thus, from the optic foramen, the optic nerve takes a tortuous, S-shaped course to the back of the globe. This longer length of the optic nerve allows movement of the eye without tension on the nerve. As mentioned, the intraorbital portion of the optic nerve increases to 3 mm in diameter due to myelination of the nerve fibers and surrounding meningeal sheaths. The orbital portion of the optic nerve lies within the muscle cone. Before passing into the optic canal, the nerve is surrounded by the annulus of Zinn, formed by the origins of the rectus muscles. The superior and medial rectus muscles partially originate from the sheath of the optic nerve. This may explain why patients with retrobulbar neuritis complain of pain when moving their eyes.[5] As previously mentioned, the optic nerve is covered by three layers: the pia mater, the arachnoid, and the dura, which sheathe the nerve and extend from the optic canal forward to the globe. The pia mater is highly vascular and is attached tightly to the optic nerve.[16, 17] The subarachnoid space is filled with CSF in continuity with the intracranial subarachnoid space. The subdural space surrounding the optic nerve, however, has no direct connection to the intracranial subdural space.[16, 17] The optic nerve is fixed to the apex of the orbit by fusion of the pia mater, the arachnoid membrane, and the dura mater to the periosteum at the optic canal.[17] At the optic canal, the dural sheath of the nerve fuses to the periosteum so that the nerve is completely immobilized.[5] The ophthalmic artery is encased by dura in the optic canal, where it lies inferolateral to the nerve. At the orbital end of the canal, it loses the dural coat and crosses medially in the intraconal space.[17]

PERIPHERAL NERVES

Several nerves reach the orbit from the middle cranial fossa and the pterygopalatine fossae. The optic nerve traverses the optic canal. Other nerves gain access to the orbit through the orbital fissures.

SENSORY INNERVATION

The major sensory innervation of the orbit is via the ophthalmic (V_1) and maxillary (V_2) divisions of the trigeminal nerve. The trigeminal nerve is the largest cranial nerve and possesses both sensory and motor divisions. The sensory portion (V_1 and V_2) subserves the greater part of the scalp, forehead, face, eyelids, eyes, lacrimal gland, extraocular muscles, ears, and dura. The motor portion innervates the muscles of mastication and the tensor tympani through the branches of the mandibular nerve. The trigeminal nuclear complex extends from the midbrain to the upper cervical segments, often as caudal as C_4.[5, 6] The cell bodies of the ophthalmic nerve are in the semilunar (Gasserian) ganglion. From the ganglion, the nerve courses along the lateral wall of the cavernous sinus, below the oculomotor and trochlear nerves, and enters the orbit through the superior orbital fissure. The ophthalmic nerve, before entering the orbit, divides into lacrimal, frontal, and nasociliary nerves, each of which enters the orbit through the superior orbital fissure.[3, 6] The frontal (largest branch) and lacrimal (smallest branch) branches of the ophthalmic nerve enter the orbit outside of the annulus of Zinn and run forward between the periorbita and the levator complex to supply the forehead and lacrimal gland. The nasociliary branch is intraconal, crosses medially over the optic nerve, continues forward along the medial wall of the orbit below the superior rectus and superior oblique muscles, and terminates as the ethmoidal (anterior and posterior) and infratrochlear nerves.[6] Its branches include one to the ciliary ganglion and two long ciliary nerves.[3, 6] The long ciliary nerves carry sympathetic vasoconstrictor fibers to supply vessels within the eyeball.[6]

Copyright © 2003, Mosby, Inc. All rights reserved.

MOTOR INNERVATION

Oculomotor Nerve (III)

The nucleus of the oculomotor nerve is in the midbrain tegmentum. The nerve appears in the interpeduncular fossa, courses above the other nerves in the most cephalic, lateral wall of the cavernous sinus, and enters the orbit through the superior orbital fissure. It has superior and inferior divisions, which are often formed before entering the orbit.[6] The nerve enters the muscle cone within the annulus of Zinn as a superior division (supplying the levator and superior rectus) and an inferior division (supplying the medial and inferior recti and the inferior oblique).

Trochlear Nerve (IV)

The nucleus of the trochlear nerve is in the midbrain tegmentum. Its fibers leave the central nervous system through the anterior medullary velum dorsally, cross to the opposite side, and pass rostrally and caudally to run in the lateral wall of the cavernous sinus between the oculomotor (III) and ophthalmic (V_1) nerves. The trochlear nerve then crosses the oculomotor nerve and passes through the superior orbital fissure above the other nerves to supply the superior oblique muscle.[5, 6]

Abducens Nerve (VI)

The nucleus of the abducens nerve is in the tegmentum of the pons. Its fibers leave the central nervous system in the ventral groove between the medulla and pons, and pass through the cavernous sinus between the internal carotid artery and the ophthalmic nerve (V_1). The abducens nerve then enters the orbit through the superior orbital fissure and passes forward on the inner surface of the lateral rectus, which it supplies.[5, 6]

OTHER NERVES

The seventh cranial nerve is the motor supply for the orbicularis oculi and its sensory division; the nervus intermedius gives the parasympathetic supply to the lacrimal gland. The facial nerve enters the parotid gland and then divides into upper temporal facial and lower cervical facial branches. It innervates the orbicularis via the upper division, which forms the temporofrontal and zygomatic branches.[3]

AUTONOMIC NERVES

The ciliary ganglion lies 1.5 to 2 cm behind the eyeball, lateral to the optic nerve and medial to the lateral rectus muscle. The ciliary ganglion measures about 1 to 2 mm in diameter. It receives sensory fibers from the nasociliary nerve, parasympathetic fibers from the oculomotor nerve, and sympathetic fibers from the internal carotid plexus in the cavernous sinus (via the superior orbital fissure).[3, 6] Only the parasympathetic fibers synapse in the ganglion. The sensory root subserves the cornea, iris, and ciliary body through short ciliary nerves that pass from the anterior part of the ciliary ganglion into the eyeball.[6] The parasympathetic fibers supply the ciliary muscle and iris sphincter (constricts pupil). The preganglionic fibers of the parasympathetics to the sphincter muscle arise in the Edinger-Westphal nucleus of the midbrain, travel with the oculomotor nerve, and run in its inferior division to end by synapsing in the ciliary ganglion. The postganglionic fibers arise from cells of the ciliary ganglion and leave the ganglion by short ciliary nerves that pierce the sclera and run to the iris. The sympathetic fibers supply ocular vessels, the iris dilator (by means of the ciliary nerves), the lacrimal gland, and the sympathetic muscles (Müller's muscles) of the upper and lower eyelids. The sympathetic fibers to the dilator pupillae muscle pass through the ciliary ganglion without synapse and run with the short ciliary nerves. The preganglionic fibers of the sympathetics to the dilator pupillae arise in the intermediolateral gray column of the upper thoracic cord, enter the sympathetic trunk, and ascend in the cervical sympathetic trunk to end by synapses in the superior cervical ganglion.[5] The postganglionic fibers arise in cells of the superior cervical ganglion and ascend through the carotid and cavernous nervous plexuses. Some fibers join the ophthalmic nerve to continue in its nasociliary branch and are carried to the eye with the long ciliary branches of this nerve. Other fibers from the cavernous plexus enter the sympathetic ''root'' of the ciliary ganglion, pass through this ganglion without synapse, and run with the short ciliary nerves.[5] Still other intraorbital sympathetic fibers travel with the oculomotor nerve to the smooth muscle component of the levator palpebrae superioris and inferior recti (Müller's muscles).[6]

The preganglionic parasympathetic fibers of the lacrimal gland arise from cells in the superior salivatory nucleus and run in the nervus intermedius with the facial nerve. They then leave the facial nerve, at the geniculate ganglion, as the greater superficial petrosal nerve, which becomes part of the nerve of the pterygoid (vidian) canal, to enter and synapse in the pterygopalatine ganglion. The postganglionic fibers arise from the cells of the pterygopalatine ganglion, pass through the pterygopalatine nerves to the maxillary nerve, and then pass through the zygomatic branch of this nerve.[5] These fibers then enter the zygomaticotemporal branch of the zygomatic nerve in the orbit and communicate with the lacrimal branch of the ophthalmic nerve to reach the lacrimal gland. The preganglionic sympathetic fibers of the lacrimal gland arise in the intermediolateral gray column of the upper thoracic cord, enter the sympathetic trunk, ascend in the cervical sympathetic trunk, and end by synapses in the superior cervical ganglion.[5] The postganglionic sympathetic fibers arise in cells of the superior cervical ganglion, pass through the carotid plexus, and continue rostrally in the deep petrosal nerve, to join the superficial greater petrosal nerve to become the pterygoid (vidian) nerve. Then the fibers pass through the pterygopalatine ganglion, without synapse, and are distributed in a manner similar to that of the postganglionic parasympathetic fibers to reach the lacrimal gland.[5]

VASCULAR ANATOMY

The major arterial supply to the orbit is from branches of the ophthalmic artery. This artery usually arises from the distal end of the cavernous sinus segment of the internal carotid artery. Rarely, it may arise from the middle meningeal artery and enter the orbit through the superior orbital fissure.[3] In the optic canal, it courses below and lateral to the optic nerve within the dural sheath, and at the orbital apex it penetrates laterally through the dura. In 82.6% of subjects it crosses to the medial orbit over the optic nerve, and in the remaining 17.4% of subjects the artery courses under the nerve.[3] The branches of the ophthalmic artery, with some variations in origin, are the lacrimal, supraorbital, anterior and posterior ethmoidal, nasofrontal, and dorsonasal arteries. The branches for the eyeball include the central artery of the retina and the ciliary arteries. The central artery of the retina is the first branch of the ophthalmic artery.[6] It crosses the optic nerve, pierces it, and runs in its center to spread over the retina.[5] The ciliary arteries are arranged in three groups: short posterior ciliary, long posterior ciliary, and anterior ciliary arteries.[5] The posterior ciliary arteries supply the globe via 15 to 20 short (to the choroid and ciliary processes and the optic nerve head) and 2 long (to the ciliary muscle, iris, and the anterior choroid) branches.[3] The long posterior ciliary arteries enter the sclera on either side of the optic nerve and run between the choroid and sclera to the ciliary body, where their branches form the anterior major arterial circle. The anterior ciliary arteries arise from the muscular branches that run with the tendons of the recti muscles and form the vascular zone under the conjunctiva. These arteries then pierce the sclera to join the major arterial circle.[5] The lacrimal artery branches into the recurrent meningeal, zygomatic, glandular, and lateral palpebral arteries (which form the arcades of the lid). The ophthalmic artery frequently has anastomotic branches to the external carotid system, by means of the middle meningeal and lacrimal arteries, which pass through the superior orbital fissure, and by means of the anterior deep temporal, superficial temporal, and lacrimal arteries.[3]

VENOUS DRAINAGE OF THE ORBIT AND EYEBALL

The venous blood from the eyeball and adjacent structures drains into the valveless inferior and superior ophthalmic veins. The superior ophthalmic vein drains into the cavernous sinus via the superior orbital fissure. The inferior ophthalmic vein passes through the inferior orbital fissure, anastomosing with the pterygoid venous plexus.[1, 3, 6] Both the superior and inferior ophthalmic veins communicate with the veins of the face.[1, 6] The superior ophthalmic vein is the larger of these two veins and arises behind the medial part of the upper eyelid by the union of a branch from the supraorbital vein and a branch from the facial vein (angular, supraorbital). The branch from the supraorbital vein enters the orbit through the supraorbital notch, while the branch from the facial vein pierces the orbital septum. The superior ophthalmic vein receives tributaries that correspond to most of the branches of the ophthalmic artery. It communicates with the central vein of the retina, and near the apex of the orbit it commonly receives the inferior ophthalmic vein. The superior ophthalmic vein also receives the two vorticose veins from the upper part of the eyeball (the vorticose veins correspond to the posterior ciliary veins). It has three sections, the first extending posterolaterally to the medial border of the superior rectus. The second section enters the muscle cone and passes superolaterally to the optic nerve and beneath the superior rectus muscle. The third section extends posteromedially along the lateral border of the superior rectus and extends to the superior orbital fissure.[3] The more variable inferior ophthalmic vein arises from a venous plexus on the anterior part of the floor of the orbital cavity. It communicates with the facial vein over the inferior orbital margin and with the pterygoid venous plexus through the inferior orbital fissure. It passes posteriorly in the orbital fat on the inferior rectus muscle and receives muscular branches and the two inferior vorticose veins from the lower part of the eyeball. The inferior ophthalmic vein often forms inferolaterally as a plexus and passes posteriorly adjacent to the inferior rectus muscle. It anastomoses with the superior ophthalmic vein and has a similar branch that connects with the pterygoid plexus through the inferior orbital fissure.[3] It may pass through the lower part of the superior orbital fissure and empty directly into the cavernous sinus.

LACRIMAL APPARATUS

The lacrimal gland lies in the superolateral angle of the orbit, in a shallow fossa (lacrimal fossa) behind the upper eyelid, and is deeply indented by the lateral border of the tendon of the levator palpebra superioris (Fig. 9-8).[1, 3, 17] The gland weighs 78 g and measures $20 \times 12 \times 5$ mm.[3] It is divided into palpebral and orbital (larger) lobes by the lateral border of the levator aponeurosis.[3] The orbital lobe is superior to the palpebral lobe. Small ducts (10 to 12) open from the deep surface of the gland into the conjunctival sac, and resection of the palpebral lobe functionally destroys the gland.[3] This is important to remember when attempting to biopsy the lacrimal gland. The borders of the gland are related anteriorly to the orbital septum, posteriorly to the periorbital fat, and medially to the superior rectus, globe, and lateral rectus (Fig. 9-8). The inferior surface rests on the lateral rectus.[3] The lacrimal gland is a serous gland. The gland has a nodular surface with a fine connective tissue pseudocapsule.[3] The gland is supported by Whitnall's ligament and by septal attachments to the superior periorbita. The lacrimal artery penetrates it posteriorly, and the vein from it drains into the superior ophthalmic vein. Its lymphatic drainage is by means of the lid and conjunctiva to the preauricular nodes.[3] The lacrimal nerve, and sometimes branches of the zygomatic nerve, carry the sensory afferents. The parasympathetic efferents are by the nervus intermedius, facial, greater superficial petrosal, vidian, sphenopalatine ganglion, infraorbital, and lacrimal nerves.[1, 3] The sympathetic efferents are from the internal carotid plexus through the sphenopalatine (pterygopalatine) ganglion. In addition to the main lacrimal gland, there are accessory glands (of Krause and Wolfring) in the lids and conjunctiva.

Copyright © 2003, Mosby, Inc. All rights reserved.

There are 20 to 40 glands of Krause in the upper fornix and 6 to 8 in the lower fornix. The glands of Wolfring are fewer, consisting of three at the upper border of the superior tarsus and one at the lower border of the inferior tarsus.[3] Tears produced by the gland pass medially toward the lacrimal puncta across the surface of the cornea, assisted by blinking of the eyelids. Evaporation of the fluid is retarded by the oily secretion of the tarsal glands. Tears are drained into the lacrimal sac through the lacrimal canaliculi of the upper and lower lids. The canaliculi originate at the puncta and have a 2 mm vertical portion and an 8 mm horizontal portion, which join into a common canaliculus. The superior canaliculus first is directed upward, then medially and downward. The inferior canaliculus first descends and then is directed medially. The common canaliculus enters the lateral wall of the lacrimal sac by means of the valve of Rösenmuller, which prevents reflux.[3] The lacrimal sac lies in the lacrimal groove, which is formed by the lacrimal bone and the frontal process of the maxillary bone.[1] The lacrimal canaliculi are lined by squamous epithelium, whereas the sac and nasolacrimal duct are lined by columnar epithelium, goblet cells, and ciliated cells. The lacrimal sac is 13 to 15 mm in vertical length. The tears drain through the nasolacrimal duct just beneath the inferior turbinate through a fold in the duct (called the *valve of Hasner*) in the lateral wall of the nasal cavity (also see Chapter 10).[3]

TECHNIQUE FOR ORBITAL CT AND MR IMAGING

General Considerations

CT and MR imaging are the two modalities commonly used for imaging the orbit. Each has advantages and disadvantages. In general, CT is the modality of choice for bony detail and for detecting calcifications and foreign bodies, but irradiation to the orbital structures is a disadvantage. The radiation dose to the lens, although less than that of a complex motion tomography orbital series, averages about 5 cGy per imaging plane. MR imaging, on the other hand, has no known biologic side effects and is superior to CT when evaluating soft-tissue detail in the globe. MR imaging is generally considered equivalent to or slightly better than CT when evaluating the orbital soft tissues. However, MR imaging should not be used for the evaluation of the orbit whenever a ferromagnetic foreign body is suspected to be present.

Computed Tomography

A routine CT examination of the orbits includes contiguous axial and coronal sectioning with a 3 mm slice thickness. When there is a suspicion of a smaller lesion, thinner sections (two 1 mm sections) should be obtained. Such thin sections are essential for optimal demonstration of the optic nerve's anatomy and pathology. Thin slices have the advantage of less volume averaging and thus provide finer spatial resolution. The radiologist should always tailor the examination according to the clinical information and the preliminary diagnosis. For foreign bodies, it is important to obtain 1.0 to 1.5 mm axial sections to increase the sensitivity for detection of smaller objects. Provided there is no patient motion, it is often unnecessary to obtain additional direct coronal sections for the localization of foreign bodies because the use of computer reformatting is helpful in producing images in other planes, especially if a multidetector scanner is utilized. For foreign bodies or lesions at the 6 or 12 o'clock position in a coronal view, it may be advisable to obtain direct coronal sections. However, the use of multidetector CT may obviate the need for such multiplanar acquisitions. For lesions of the globe, thin sectioning (1.0 to 1.5 mm) is exceedingly important, because one can easily miss an ocular lesion on routine 5 mm sections.[17] For bony lesions or orbital fractures, in addition to the routine study, retrospective high-resolution extended bone scale images should be obtained (4000 ms window width, 700 to 800 window level).[17]

For orbital CT scanning, the need for intravenous (IV) contrast medium administration should be determined by the clinical information and is best left to the discretion of the radiologist. Contrast material uniformly increases the density of most intraorbital soft-tissue structures.[18] Although it is not always easy to discriminate between orbital lesions based on their patterns of enhancement, contrast material is often necessary to evaluate their vascular characteristics and, more importantly, to evaluate any intracranial extension of an orbital lesion. Not uncommonly, an apical orbital mass may be an extension of an intracranial lesion such as a meningioma, which can be readily missed on a noncontrast CT study. In general, a contrast medium is not used when evaluating for foreign bodies, uncomplicated orbital fractures, uncomplicated thyroid ophthalmopathy, morphologic changes in or variations of the extraocular muscles, dermoid cysts (noninfected and unruptured), and bony lesions such as osteoma, osteoid osteoma, fibrous dysplasia, and Paget's disease. Contrast-enhanced CT is usually necessary in patients with osteogenic or chondrogenic sarcomas or metastatic bone disease.

The axial sections normally are obtained roughly parallel to the infraorbital-meatal line.[17, 18] This can be easily determined by obtaining a lateral digital scout view (scanogram). The inferior section should include the upper portion of the maxillary sinuses, and the upper section should include the sella and the entire frontal sinuses. For all orbital and ocular tumors, additional postcontrast 10 mm axial sections of the remainder of the head are usually obtained. Although brain metastasis from orbital and ocular tumors is uncommon, the additional sections may provide information about unsuspected lesions (meningioma, aneurysm, and arteriovenous malformation).[17] The coronal sections are obtained roughly perpendicular to the infraorbital-meatal line. However, in many instances, the angle of the coronal sections is made more oblique (semicoronal) when the patient has many dental fillings or other metallic prostheses. Patient positioning for imaging in the coronal plane can be in either the prone or supine position, and as for the axial sections, the coronal plane study can be determined easily by obtaining a lateral digital scout view of the orbit. The coronal examination of the orbits should be tailored according to the clinical information and the findings on the axial sections. In patients suffering from visual loss and when evaluating the

Copyright © 2003, Mosby, Inc. All rights reserved.

intracranial extension of an apical lesion, the coronal sections should be extended posteriorly to include the optic chiasm. For lesions involving the anterior ethmoid air cells and nasal cavity, and for lesions arising from the nasolacrimal sac and duct, coronal sections should be extended anteriorly to include the nasal bones.

Almost all CT scanners are capable of performing computer reformation of compiled data from axial sections into coronal, sagittal, or oblique planes. Although the quality of the images may be inferior to those obtained with direct scanning, in many instances additional information can be obtained, particularly if high-quality, thin (1.5 to 3 mm) direct axial or coronal sections are available. It should be noted, however, that the quality of such images on the newer multidetector CT scanners is excellent. If a multidetector scanner is not available, direct sagittal plane scans of the craniofacial structures can be achieved by laying the patient on a separate support and using a special head holder that is fitted to the standard tabletop.[19, 20]

MR Imaging Techniques

Almost all of the MR images presented in this section were obtained with a 1.5 Tesla Signa unit (General Electric, Milwaukee). Using a head coil, single echo spin-echo (SE) pulse sequences were obtained with a repetition time (TR) of 400 to 800 ms and an echo time (TE) of 20 to 25 ms (TR/TE, 400 to 800/20 to 25 ms). Multiecho SE pulse sequences were obtained with a TR of 1500 to 2800 ms and a TE of 20 to 100 ms. Although each examination should be specifically tailored to the patient's problem, the routine MR imaging examination of the orbit should include short TR, short TE sagittal images, 4 to 5 mm in thickness with 1 to 1.5 mm intersection spacing, using the routine head coil. These studies were most often performed with one excitation, a 256×192 or 256×256 matrix size, and a 20 to 24 cm field of view. Following the sagittal T1-weighted scans, an axial multiecho SE sequence (TR/TE 2000 to 2800/20, 80 ms) was obtained to include the entire orbital structures. For this multiecho SE pulse sequence, a section thickness of 4 to 5 mm with a 1.5 to 2.5 mm intersection gap was used, with a matrix size of 256×192 and a 20 cm field of view. An additional single echo or multiecho SE sequence in the coronal plane was obtained according to the findings on the sagittal and axial sections. Because T1-weighted images provide more spatial resolution than T2-weighted images, if more anatomic detail is essential, coronal T1-weighted images are preferred. On the other hand, T2-weighted images provide more contrast resolution than T1-weighted images, and if there is a need for more pathologic detail, coronal multiple SE pulse sequences are obtained (TR/TE, 2000/20, 80 ms). For optic nerve lesions, additional parasagittal images are obtained by using a head coil. For some of the orbital lesions, additional images were obtained using a surface coil. Images with a surface coil provide better spatial resolution than images obtained with a head coil. However, because of signal dropout, an apical lesion or intracranial extension of an orbital lesion cannot be fully evaluated. Paramagnetic contrast material, a gadolinium complex of diethylenetriamine pentaacetic acid (Gd-DTPA), should be used for suspected orbital abscesses, meningiomas, schwannomas, neurofibromas, hemangiopericytomas, fibrous histiocytomas, lacrimal gland tumors, metastases, lymphomas, pseudotumors, other specific or nonspecific orbital masses, and optic nerve lesions including optic neuritis. Contrast-enhanced, T1-weighted studies were obtained with an axial SE 600 to 800/20 (TR/TE) sequence with four excitations, a 16 to 20 cm field of view, and a 256×128 matrix size. Section thickness was 3 mm with a 0.5 mm intersection gap. A precontrast T1-weighted axial SE sequence was always obtained. This pulse sequence was identical to the postcontrast T1-weighted sequence, except that two rather than four excitations were used.

Inversion Recovery and Application of Fat-Suppression Technique

Short tau inversion recovery (STIR) images result in very high lesion conspicuity by suppressing the signal from fat and by adding T1-weighted and T2-weighted information together. Because most pathology has a long T1 and T2 relaxation time, pathology appears with a high signal intensity on STIR. Further, the lower fat signal intensity makes any pathology stand out. The optimal TI (time of inversion) for fat suppression may vary from one individual to another, depending on coil loading and fat composition. The optimal TI for fat suppression at 1.5 Tesla is in the 145 to 170 ms range. Usually the STIR image is obtained with a TR of 2000, a TI of 150 to 160, and a TE of 20 ms.

T1-Weighted Fat-Suppression Technique

Fat-suppressed T1-weighted images may be obtained using various techniques.[21, 22] In this chapter, fat-suppressed T1-weighted images were obtained using a presaturation technique. Before imaging, the spectral fat peak was determined in each patient. Subsequently, an RF pulse was applied, centered at the resonant frequency of fat. The RF pulse was followed by a spoil gradient. This fat-suppression technique (chemsat) is a standard feature on the Signa system and can be easily applied in the same time required for a standard T1-weighted sequence. After the postcontrast fat-suppressed images were obtained, a standard T1-weighted sequence in either the axial or coronal plane, with the same parameters used for the fat-suppressed T1-weighted images, was immediately obtained. This was done because the fat-suppression pulse sequences are more sensitive to magnetic susceptibility artifacts.[21–23] In addition, the enhancement of the extraocular muscles, and in particular the lacrimal glands, is exaggerated on the fat-suppressed images. There is thus the possibility of misinterpreting a lesion if it is adjacent to the lacrimal gland, the extraocular muscles, or the walls of the sinuses (air–bone–soft-tissue interface).[17]

Normal CT and MR Imaging Anatomy

The bony landmarks can be visualized best on CT with the aid of the bone extended scale and bone window technique (Fig. 9-9). The optic canal can be seen on both axial and coronal scans. The lateral and medial bony orbital margins, the superior and inferior orbital fissures, the lacrimal fossa, lacrimal sac, nasolacrimal canal, infraorbital canal, and paranasal sinuses are also equally well seen on

VIEW IMAGE

axial or coronal scans (Fig. 9-9). Coronal scans are best for assessing the floor and roof of the orbits. The lamina papyracea is a paper thin plate of bone that forms most of the medial orbital wall, separating it from the adjacent ethmoid air cells. This plate often appears to be dehiscent on CT, and therefore care should be taken not to make an erroneous diagnosis of bone destruction or fracture.

Extraocular Muscles

The extraocular muscles are well visualized on CT, and they are uniformly enhanced on postcontrast CT scans (Figs. 9-10 to 9-13). These muscles are also seen well on MR imaging (Figs. 9-14 to 9-26). The extraocular muscles generally have a course parallel to that of the adjacent orbital wall. Consequently, only the horizontal recti (lateral and medial) may be seen in their entirety in the axial plane (Figs. 9-12 and 9-16). Likewise, the vertical recti (inferior and superior) may be seen best in the parasagittal (oblique) plane (Figs. 9-6, 9-7, and 9-27). The tapering of these muscles in

VIEW IMAGE

their tendinous portions and their origins at the annulus of Zinn are seen well in the parasagittal (vertical recti) and axial (horizontal recti) planes (Figs. 9-6 and 9-16). The superior and inferior recti are only partially visualized in any one axial plane (Figs. 9-14, 9-15, 9-20, and 9-21). On coronal scans, all of the recti muscles are seen in an oblique cross section (Figs. 9-22 and 9-24) related to their slanted orientation to the coronal plane as the walls of the orbit slant toward the orbital apex. For accurate determination of the cross-sectional size of these muscles, reformatted images or direct oblique MR imaging would have to be done separately for each muscle. This is obviously not practical, nor is it necessary unless there is a critical situation requiring the precise size of a particular muscle.[15] The levator palpebrae superioris is closely approximated to the superior rectus muscle, and it is identified as a separate muscle only on anterior coronal images (Fig. 9-22), where it diverges from the superior rectus. These two muscles can be visualized as separate muscles on sagittal and parasagittal (oblique) MR imaging (Fig. 9-27). The muscle portion of the superior oblique muscle can be visualized best on coronal scans, and its tendinous portion is seen best on axial scans (Figs. 9-11, 9-13, and 9-23). The reflected portion of the superior oblique muscle and its tendon are seen best on axial scans (Figs. 9-13 and 9-20). The trochlea is seen well on axial scans, and it is occasionally calcified. The inferior oblique muscle is seen best on coronal, sagittal, and parasagittal scans (Fig. 9-10). On axial scans the muscle belly is poorly seen, but its insertion is well visualized.

Orbital Compartments

In descriptive terms, the orbit has been divided into the extraperiosteal, subperiosteal, extraconal, conal, and intraconal spaces (Boxes 9-1 to 9-3). The intraconal space is separated from the other spaces by the rectus muscles and their intermuscular septa, which are denser in the anterior orbit and are seen best on coronal scans (Figs. 9-22 and 9-23). Because certain lesions have a predilection to present

in a specific orbital space, the concept of the orbital spaces has some practical value. It is useful for radiologic differential diagnosis and for surgical planning, and these lesions are discussed later in this chapter. The distinction of intraocular and extraocular locations within the orbit is also useful when evaluating metastatic and dystrophic orbital calcifications (Boxes 9-4 and 9-5).

Lacrimal Gland

With the exception of a portion of the superior ophthalmic vein, the lacrimal glands are the only prominent structures readily identified in the superolateral extraconal space.[18] Each lacrimal gland is about the size and shape of an almond. It is adjacent to the tendons of the superior and lateral rectus muscles and is separated from the globe by the lateral rectus muscle (Figs. 9-10, 9-13, and 9-19). The more anterior palpebral lobe is separated from the deeper orbital lobe by the lateral horn of the levator muscle aponeurosis.[24]

Vascular and Neural Structures

Although the vascular structures in the orbit frequently can be seen on noncontrast CT, they are highlighted with

contrast. On MR imaging the larger vessels usually have low signal intensity (signal void). The ophthalmic artery can be seen in the apex of the orbit on the inferior aspect of the optic nerve and then as it swings laterally before looping around and over the optic nerve to its superior medial aspect (Fig. 9-24). Several of its branches, including the anterior and posterior ethmoidal and posterior ciliary branches, usually can be identified.[3, 25, 26]

The superior ophthalmic vein originates in the extraconal space, in the anteromedial aspect of the orbit. It then courses near the trochlea to pass through the muscle cone beneath the superior rectus muscle and above the optic nerve. It then exits the intraconal space through the superior orbital fissure (Figs. 9-19 and 9-20). This vein is routinely identified in axial, coronal, sagittal, and parasagittal images. The inferior ophthalmic and connecting veins are seen inconsistently.[3] The intraconal and extraconal components of the small nerves of the orbit, particularly the frontal, supraorbital, and inferior divisions of the third nerve, as well as the infraorbital nerve, may be identified on CT. These nerves are identified better on MR imaging. The position of these nerves may be variable.[3] The frontal nerve can be seen between the levator palpebrae superioris muscle and the orbital roof (Figs. 9-22 and 9-23). Most of these small nerves can be seen on coronal scans of the orbital apex (Fig. 9-22).[26]

Optic Nerve

The optic nerve arises from the ganglionic layer of the retina and consists of coarse myelinated fibers, like the white matter of the central nervous system.[1, 6, 16] The orbital segment of the optic nerve is 3 to 4 mm in diameter and 20 to 30 mm long (Fig. 9-18). It has a serpiginous course (with minimal inferior and lateral bowing in its midportion) in the orbit, which allows unrestricted movement of the globe. From its insertion on the posterior globe, it courses posteriorly, medially, and superiorly to exit the orbit at the optic canal. The optic nerve is covered by layers of pia, subarachnoid membrane, and dura mater. All these layers fuse as they approach the globe, becoming continuous with the sclera. The intracranial subarachnoid space extends around the optic nerve, ending at the sclera. The subdural space is a potential space and is not considered to be continuous with the intracranial subdural space. At the superior aspect of the intracanalicular portion of the optic nerve, the three layers of covering are fused to each other and to the optic nerve. The dural layer is fixed to the periosteum of the optic canal, protecting it from back-and-forth motion.[17] The intracranial segment of the optic nerve is located medially and then above the internal carotid artery in the suprasellar region (Fig. 9-18). The optic nerves join in the suprasellar cistern to form the optic chiasm (Fig. 9-18). The subarachnoid space around the optic nerve sheath has a low density on CT and can be imaged during the course of iodinated contrast cisternography. The meningeal layers of the optic nerve show enhancement on postcontrast CT. On coronal scans, immediately posterior to the globe, a small central density within the nerve represents the central retinal artery and vein.[3] The optic nerve and sheath measure 3 to 5 mm in the axial plane and 4 to 6 mm in the coronal plane.[17] The intracanalicular and prechiasmatic portions of the optic nerve are particularly well demonstrated by MR imaging (Fig. 9-18). Generally, on T1-weighted, proton density, and T2-weighted images, the optic nerve has signal intensities similar to those of normal white matter.[27] A ring of T1-weighted hypointensity and T2-weighted hyperintensity, representing CSF within the nerve sheath, is frequently seen on coronal sections. This should not be confused with well-defined areas of hypointensity bordering the nerve, which are caused by chemical shift artifact.

Globe

The three ocular coats (sclera, choroid, and retina) form a well-defined line on CT that enhances with IV contrast. The lens is normally hyperdense on CT, and the vitreous appears hypodense and shows no contrast enhancement. On MR imaging the ocular coats appear as a hypointense ring, and the vitreous has characteristics very similar to those of CSF. The lens is isointense to vitreous (low signal intensity) on T1-weighted images and has very low signal intensity on T2-weighted images. These signal intensities reflect the high

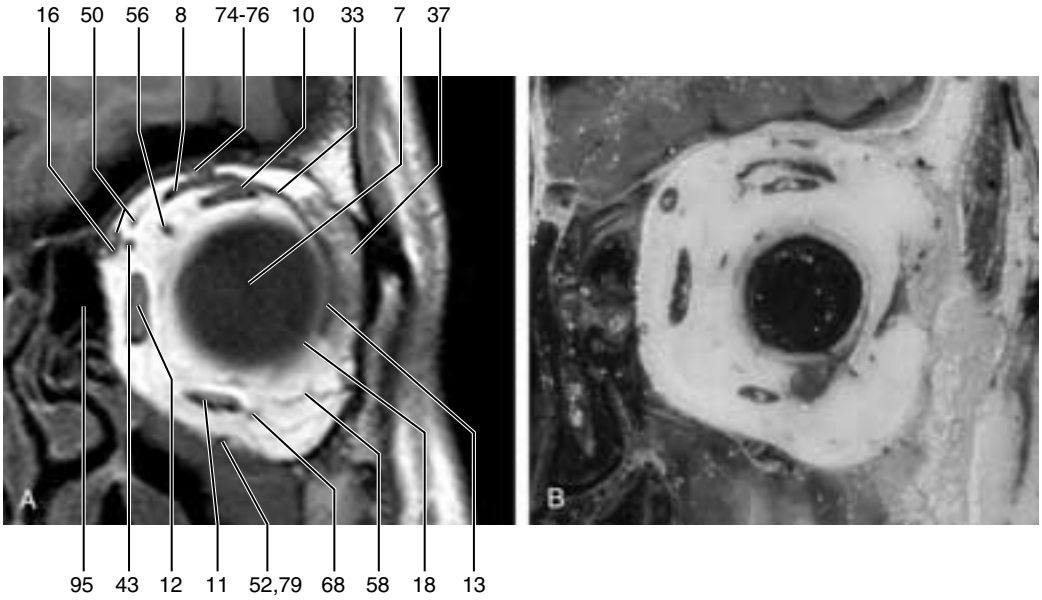

FIGURE 9-23 Normal MRI anatomy. Coronal T1-weighted MRI shows inferior rectus muscle (*1*); medial rectus muscle (*2*); superior oblique muscle (*3*); superior rectus muscle (*4*); levator palpebrae superioris (*5*); partially volumed lacrimal gland (*6*); lateral rectus (*7*); presumed branch of oculomotor nerve (*8*); collateral vein (*small arrowheads*); medial ophthalmic vein (*solid black arrow*); frontal nerve/supraorbital nerve (*hollow arrow*); supraorbital/ophthalmic artery (*single arrowhead*); vitreous (*V*); and maxillary antrum (*M*).

protein and liquid crystal composition of the lens. The imaging of the globe is discussed in detail in Chapter 8.

BONY INTERORBITAL DISTANCE

The distance between the orbits and their individual dimensions are important in the diagnosis of craniofacial anomalies. The orbits are often involved in craniofacial malformations, which include orbital clefts, orbital hypotelorism, and hypertelorism, and measurement of the bony interorbital distance (BID) is useful in establishing the severity of hypertelorism. This distance between orbits is commonly measured at the interdacryon level, the dacryon being the point of junction of the nasal bone, lacrimal bone, and maxilla.[19] Before CT, most observers relied on standard radiographs for measuring the BID, and normal values for adults and the younger age groups are available.[28-32] The BID was first defined by Cameron, in a small number of dried skulls, as the maximum distance between the medial

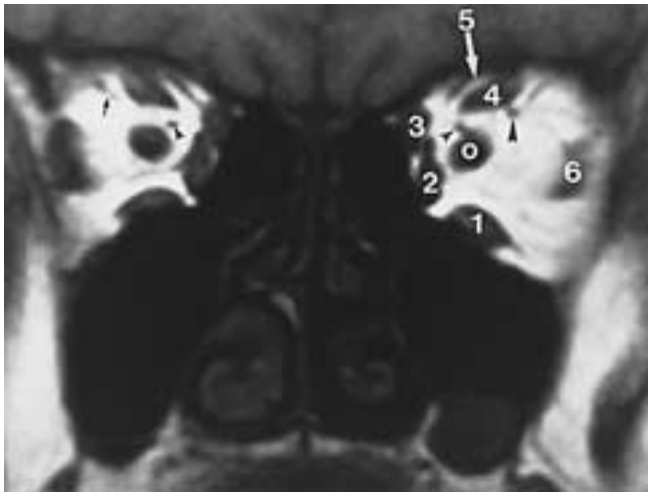

FIGURE 9-24 Normal MR imaging anatomy. T1-weighted MR coronal image shows the inferior rectus muscle (*1*); medial rectus muscle (*2*); superior oblique muscle (*3*); superior rectus muscle (*4*); levator palpebrae superioris (*5*); lateral rectus muscle (*6*); optic nerve (*o*); superior ophthalmic vein (*large arrowhead*); ophthalmic artery (*small arrowhead*); and lacrimal nerve (*black arrow*).

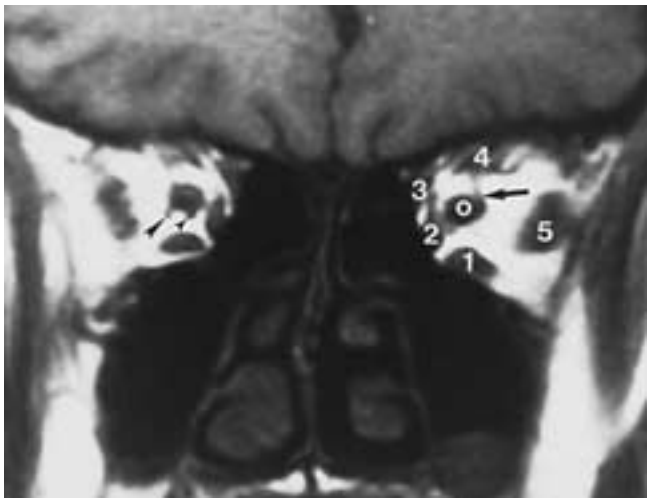

FIGURE 9-25 Normal MR imaging anatomy. T1-weighted MR coronal image shows the inferior rectus muscle (*1*); medial rectus muscle (*2*); superior oblique muscle (*3*); superior rectus muscle (*4*); lateral rectus muscle (*5*); optic nerve (*o*); long posterior ciliary arteries (*arrowheads*); and presumed ciliary ganglion (*arrow*).

VIEW IMAGE

FIGURE 9-26 Normal MR imaging anatomy. T1-weighted MR coronal image shows the lesser (*double solid arrows*) and greater (*double hollow arrows*) wings of the sphenoid bone, medial rectus muscle (*single hollow arrow*); inferior rectus muscle (*long arrow*); lateral rectus muscle (*large white arrowhead*); superior muscle complex (*black arrowheads*); optic nerve (*short white arrowhead*); and fat in the apex of the orbit, along with the inferior orbital fissure (*curved arrow*). The common tendon of Zinn is seen as areas of hypointensity between the rectus muscles. The relative position of the nerves, veins, and ophthalmic artery entering orbital cavity through superior orbital fissure cannot be precisely resolved with current MR imaging technology.

BOX 9-1
INTRACONAL (CENTRAL ORBITAL) LESIONS

More Common

- Cavernous hemangioma
- Optic nerve meningioma
- Optic nerve glioma
- Optic nerve granulomatous disease (sarcoid)
- Optic neuritis (multiple sclerosis)
- Lymphoma
- Pseudotumor
- Lymphangioma
- Venous angioma
- Varix
- Arteriovenous malformation
- Carotid cavernous fistula
- Hemangiopericytoma
- Rhabdomyosarcoma
- Metastasis
- Orbital cellulitis and abscess

Less Common

- Capillary hemangioma
- Peripheral nerve tumors
  - Neurofibroma
  - Schwannoma
- Leukemia
- Hematocele
- Optic nerve sheath cyst
- Colobomatous cyst
- Hemangioblastoma (optic nerve)
- Chemodectoma (ciliary ganglion)
- Necrobiotic xanthogranuloma
- Lipoma
- Amyloidosis
